## Chapter 1

### Background

In this section, we cover the background subjects needed to formally pose the problem and present solutions in this thesis. We start with two types of combinatorial structures, linkages and polygonal linkages. We then discuss the configuration spaces of linkages and polygonal linkages. We then look into an alternate representation of linkages, disk arrangements and state the disk arrangement theorem. We then look at satisfiability problems and then review a framework, the logic engine, which can encode a type of satisfiability problem. Finally, we cover the basic definitions of algorithm complexity for **P** and **NP**.

#### 1.1 Graphs

A *graph* is an ordered pair  $G = (V, E)$  comprising of a set  $V$  of vertices and a set  $E$  of edges or lines. Every edge  $e \in E$ , is an unordered pair of distinct vertices  $u, v \in V$  ( the edge represents their adjacency,  $e = \{u, v\}$ ). With this definition of a graph, there are no loops (self adjacent vertices,  $\{v, v\}$ ) or multi-edges (several edges between the same pair of vertices).

A motivation for using graphs is modelling physical objects like molecules. This requires an embedding into the plane or  $\mathbb{R}^3$ . An *embedding* of the graph  $G = (V, E)$  is an injective mapping  $\Pi : V \mapsto \mathbb{R}^2$  (see Figure 1.1).

Figure 1.1: An embedding of the Peterson graph.

##### 1.1.0.1 Edge Crossings

We define *plane embeddings* of a graph to be an embedding where the following degenerate configurations do not occur:

- (i) the interiors of two or more edges intersect, or
- (ii) an edge passes through a vertex

Figure 1.2: These figures exhibit the 4 types of edge crossings.

A graph is called *planar* if it admits a plane embedding. A *plane graph* is a graph together with a plane embedding.

### 1.1.1 Trees

A *path* is a sequence of vertices in which every two consecutive vertices are connected by an edge. A *simple cycle* of a graph is a sequence,  $(v_1, v_2, \dots, v_{t-1}, v_t)$ , of distinct vertices such that every two consecutive vertices are connected by an edge, and the last vertex,  $v_t$ , connects to  $v_1$ . A graph is *connected* if for any two vertices, there exists a path between the two points.

A *tree* is a graph that has no simple cycles and is connected.

### 1.1.2 Ordered Trees

An *ordered tree* is a tree together with a cyclic order of the neighbors for each vertex. Embeddings of ordered trees are equivalent if for each node the counter-clockwise ordering of adjacent nodes are the same.

### 1.1.3 Graph Isomorphism

To determine when two graphs are equivalent, we need to define an isomorphism for graphs. Given two graphs  $G_1 = (V_1, E_1)$  and  $G_2 = (V_2, E_2)$ , a *graph isomorphism* is a bijective function  $f : V_1 \mapsto V_2$  such that for any two vertices  $u, v \in V_1$ , we have  $\{u, v\} \in E_1$ , if and only if  $(f(u), f(v)) \in E_2$ .

(a) An embedding of the Petersen graph with a simple cycle of  $(2, 7, 9, 6, 1, 0, 5, 8, 3, 2)$ .

Figure 1.4: A tree with two embeddings with different cyclic orderings around vertices.

Graph	Vertices	Edges
$G_1$	$\{a, b, c, d, e\}$	$\{ab, (b, c), (c, d), (d, e), (e, a)\}$
$G_2$	$\{1, 2, 3, 4, 5\}$	$\{(1, 2), (2, 3), (3, 4), (4, 5), (5, 1)\}$

Table 1.1: Two graphs that are isomorphic with the alphabetical isomorphism  $f(a) = 1, f(b) = 2, f(c) = 3, f(d) = 4, f(e) = 5$ .

Figure 1.5: This figure depicts the graph isomorphism shown in Table (??) between  $V_1$  and  $V_2$  in the plane.

## 1.2 Linkages

Figure 1.6: An embedded linkage

When graphs model physical objects, distances between adjacent vertices matter. The length assignment of a graph  $G = (V, E)$  is  $\ell : E \mapsto \mathbb{R}^+$ . A *linkage* is a graph  $G = (V, E)$  with a length assignment  $\ell : E \mapsto \mathbb{R}^+$ .

We consider embeddings of a graph that respects the length assignment. A *realization* of a linkage,  $G$  and  $\ell$ , is an embedding of a graph,  $\Pi$ , such that for every edge  $\{u, v\} \in E$ ,  $\ell(\{u, v\}) = |\Pi(u) - \Pi(v)|$ . A *plane realization* is a plane embedding with the property,  $\ell(\{u, v\}) = |\Pi(u) - \Pi(v)|$ .

## 1.3 Polygonal Linkages

Figure 1.7: (a) A polygonal linkage with a non-convex polygon and two hinge points corresponding to three polygons. Note that hinge points correspond to two distinct polygons. (b) Illustrating that two hinge points can correspond to the same boundary point of a polygon.

A generalization of linkages are polygonal linkages where the edges of given lengths are replaced by rigid polygons. Formally, a *polygonal linkage* is an ordered pair  $(PP, \mathcal{H})$  where  $PP$  is a finite set of polygons and  $\mathcal{H}$  is a finite set of hinges; a *hinge*  $h \in \mathcal{H}$  corresponds to two points on the boundary of two distinct polygons in  $PP$ . A *realization* of a polygonal linkage is an interior-disjoint placement of congruent copies of

the polygons in PP such that the points corresponding to each hinge are identified (Fig. ??). This definition of realization rules well known geometric dissections (e.g. Fig. 1.8).

Figure 1.8: Two configurations of polygonal linkage where the polygons touch on boundary segments instead of hinges. These two realizations of the polygonal linkage are invalid to our definitions.

Figure 1.9: (a) A polygonal linkage with a non-convex polygon and a hinge point corresponding to three polygons. (b) A polygonal linkage with 8 regular polygons.

### 1.3.1 Disk Arrangements

It turns out the disk arrangements are an equivalent way to to represent plane graphs. By representing vertices as interior disjoint disks and by representing edges as as points of intersections (contact), *kissing points* between two disks. The graph corresponding to a given disk arrangement,  $\mathcal{D}$ , is said to be the *contact graph*. A *disk arrangement* is a set,  $\mathcal{D}$ , of pairwise interior-disjoint disks in the plane,  $\mathcal{D} = \{C_i\}_{i=1}^n$ .  $\{C_i\}_{i=1}^n$  such that for any circle  $C \in \{C_i\}_{i=1}^n$ ,  $C$

A classical result by Thurston and Koebe is that every disk arrangement embedded into the plane had a corresponding plane graph.

**Theorem 1.3.1** (Disk Packing Theorem). *For every graph  $G$ , there is a disk arrangement in the plane whose contact graph is isomorphic to  $G$ .*

**Proposition 1.3.1.** *For every linkage  $L$ , there is a disk arrangement in the plane whose contact graph is isomorphic to  $L$ .*

1. Show the relation between polygonal linkages and disk arrangements.

#### 1.3.1.1 Ordered Disk Arrangement

Suppose we're given a tree. By the disk packing theorem we can ascertain a sense of order for the isomorphic disk packing. An *ordered disk arrangement* is a rooted tree in which the counter-clockwise ordering of adjacent vertices.

Figure 1.10: This example represents a disk arrangement transformed to and from its corresponding graph  $G_2$

### 1.3.1.2 Disk Packing Confinement Problem

Given inputs of radii By adding constraints to the embeddings of disk arrangements, we can devise realizability problem by a volume argument.

1. Round 1: Start with a disk of unit radius.
2. Round 2: Add two kissing disks, each of diameter 2, that do not intersect with any other disk (they may kiss other disk).
3. Round 3 and Higher: For each new kissing disk added, add two more non-intersecting kissing disks of diameter 2 to it.

For each round  $i$  we are adding  $2^{(i-1)}$  disks, each with an of  $\pi$ . The area that the disk arrangement is bounded by at round  $i$  is a box of length  $2 \cdot (2 \cdot (i-1) + 1)$  totalling to an area of  $(4 \cdot i^2 - 4 \cdot i + 1)$ . Meanwhile the total area of the disk arrangement at round  $i$  is  $\pi \cdot (2^i - 1)$ . The exponential growth rate of the disk packing will exceed its bounded area for sufficiently large  $i$ .

Figure (1.11) illustrates the iterative problem. The problem with this is that the area in which is necessary to contain this disk growing disk arrangement will exceed the area needed to contain it.

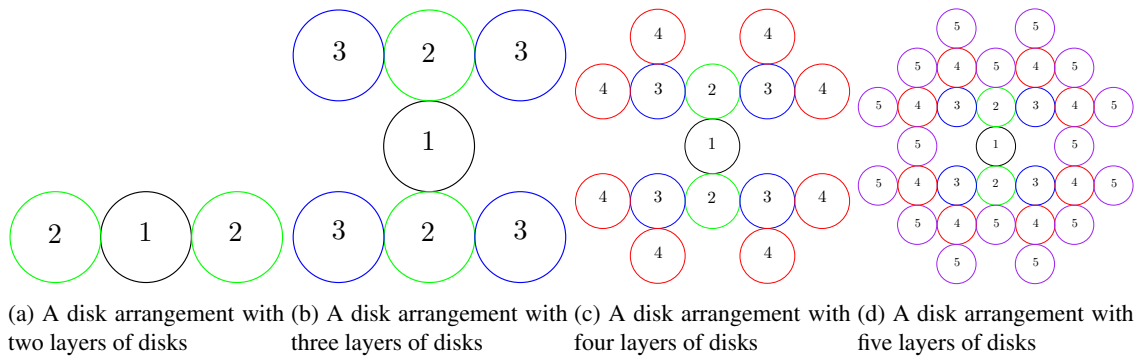

Figure 1.11: The gradual growth of disk arrangements by adding two kissing disks to each of the previously generated disks. By continuing this arrangement growth, the space needed to contain the kissing disks will exceed the area containing the disk arrangements.

## 1.4 Configuration Spaces

Just as one can compose colors or forms, so one can compose motions.

Alexander Calder, 1933

We'd like to describe motions and range of motions of embedded graphs, linkages, polygonal linkages, and disk arrangements. Table 1.4 provides the definition of *reconfiguration* for each type of object covered so far:

Object Type	Definition of Reconfiguration
Graph	a continuous motion of the vertices that preserves the lengths of the edges and never causes the edges to intersect.
Linkage	same as graph
Polygonal Linkage	a continuous motion of polygons that preserves shapes of polygons, hinge point pairings, and never causes the polygonal sides to intersect.
Disk Arrangement	a continuous motion of disks that preserves disk radii, pairs of contact points, and never causes disks to intersect.

### 1.4.1 Configuration Spaces of Linkages

Let's focus on the space of embeddings of a linkage. If there are  $n$  vertices of a linkage, the *configuration space* of a linkage is said to be a vector space of dimension  $2 \cdot n$  where edge length is preserved. A *configuration space* for a linkage  $G$  and corresponding proper embedding,  $L_1$  is said to be for any other

Figure 1.12: (a) and (b) show a linkage in two embeddings.

proper embedding of a linkage  $G$ ,  $L_2$ , such that the lengths of every edge of  $G$  is preserved between the two embeddings, i.e.:

$$l((u, v)) = |L_1(u) - L_1(v)| = |L_2(u) - L_2(v)|$$

Equivalent embeddings include translations and rotations about the center of mass on  $L(V)$ . We further our embeddings by requiring that one vertex is pinned to the point of origin on the plane as well as a neighboring

vertex.

**Theorem 1.4.1** ([?, ?]Carpenter's Rule Theorem). *Every realization of a linkage can be continuously moved (without self-intersection) to any other realization. In other words, the realization space of such a linkage is always connected.*

Figure 1.13: A linkage whose complete configuration space is discontinuous. These two examples above are two configurations of the same linkage that cannot continuously transform into the other without edge crossing.

A *reconfiguration* of a linkage whose graph is  $G = (V, E)$  and length assignment is  $\ell$  is a continuous function  $f : [0, 1] \mapsto \mathbb{R}^{2 \cdot |V|}$  specifying a configuration of the linkage for every  $t \in [0, 1]$  where length assignment  $\ell$  is preserved, edges do not cross and for every  $\varepsilon > 0$ , there exists a  $\delta > 0$  such that  $|t_1 - t_2| < \delta$  implies

$$|f(t_1) - f(t_2)| < \varepsilon$$

## 1.4.2 Configuration Spaces of Polygonal Linkages

Some text goes here

## 1.4.3 Configuration Spaces of Disk Arrangements

Figure 1.14: A linkage whose complete configuration space is discontinuous. These two examples above are two configurations of the same linkage that cannot continuously transform into the other without edge crossing.

## 1.5 Algorithm Complexity

*Algorithms* are a set of procedural calculations. When an algorithm executes its procedure it can be measured in terms of units of consumed resources (in computers, that is memory) and the time it takes to complete the procedure of calculations. Ideally, a desirable algorithm would run quickly and utilizes a small amount of resources.

### 1.5.1 Qualitative Analysis of Algorithms

Determining the time and space that algorithms use determine their efficiency. The *worst-case* running time is the largest possible running time that an algorithm could have over all inputs of a given size  $N$ . *Brute force* is when an algorithm tries all possibilities to see if any formulates a solution. An algorithm is said to be *efficient* if it achieves qualitatively better worst-case performance, at an analytical level, than brute force search.

### 1.5.2 Categorization of Algorithms

For combinatorial problems, as the number of inputs of the problem grows, the solution space tends to grow exponentially. In general, as problems grow, it is desirable to minimize the *running time*, time take to run an algorithm that solves a problem. Formally, we quantify running time with Big O notation.

**Definition 1.5.1** (Big O Notation). Let  $f$  and  $g$  be defined on some subset of  $\mathbb{R}$ .  $f(x) = O(g(x))$  if and only if there exists a positive real number  $M$  and  $x_0$  such that

$$|g(x)| \leq M|f(x)|$$

for all  $x \geq x_0$

#### 1.5.2.1 P and NP

An algorithm has a *polynomial running time* if there is a polynomial function  $p$  such that for every input string  $s$ , the algorithm terminates on  $s$  in at most  $O(p(|s|))$  steps.

To categorize problems [?], we ask the following:

**Problem 1.5.1.** Can arbitrary instances of problem  $Y$  be solved using a polynomial number of standard computational steps, plus a polynomial number of calls to an algorithm that solves  $X$ ?

The class of problems that can be solved in polynomial running time is called the *polynomial time* class, P. A second property of problems is whether if its solution can be verified efficiently. This property is independent of whether it can be solved efficiently.  $B$  is said to be an efficient certifier for a problem  $X$  if the following properties hold:

- (i)  $B$  is a polynomial-time algorithm that takes two inputs  $s$  and  $t$ .
- (ii) There exists a polynomial function  $p$  such that for every string  $s$ , we have  $s \in X$  if and only if there exists a string  $t$  such that  $|t| \leq p(|s|)$  and  $B(s, t) = \text{'yes'}$ .

The class of problems which have an efficient certifier is said to be the *nondeterministic polynomial time* class, NP. Before we continue with the definitions for NP and NP complete, we will look into a type of problem, a reduction of a problem, and what an efficient certification is. This facilitates the reader for the definitions and illustrate complexity better.

### 1.5.3 Reduction

A *polynomial time reduction* is when arbitrary instances of problem  $Y$  be solved using a polynomial number of standard computational steps, plus a polynomial number of calls to a black box that solves problem  $X$ . To illustrate what a reduction is, we cover an example of independent sets and vertex covers. Given a graph  $G = (V, E)$ , a set of vertices  $S \subset V$  is *independent* if no two vertices in  $S$  are joined by an edge. A *vertex cover* of a graph  $G = (V, E)$  is a set of vertices  $S \subset V$  if every edge  $e \in E$ , has at least one end corresponding in  $S$ .

**Theorem 1.5.1.** *Let  $G = (V, E)$  be a graph. Then  $S$  is an independent set if and only if its complement  $V - S$  is a vertex cover.*

**Proof 1.5.1.** *If  $S$  is an independent set. Then for any pair of vertices in  $S$ , the pair are not joined by an edge if and only if for any  $v_1, v_2 \in S$ ,  $e = (v_1, v_2) \notin E$ . We have two cases. The first case is if  $v \in S$ , then any vertex  $u \in V$  that forms an edge  $e = (v, u) \in E$  must reside in  $V - S$ . The second case is if there is an edge which no pair of vertices is in  $S$ , then both vertices are in  $V - S$ . Both cases together imply that every edge has at least one end corresponding in  $V - S$ .*

*If  $V - S$  is a vertex cover. Every edge  $e \in E$  has at least one vertex in  $V - S$ . The two possible cases, the first case is that the second vertex is in  $V - S$ , and the second case is that the second vertex is in  $S$ . The first case would yield  $S = \emptyset$ . The second case implies that the edge  $e \in E$  has exactly one vertex in  $V - S$  and exactly one vertex in  $S$ .  $V - S$  is a vertex cover would disallow  $S$  to have a pair of vertices to form an edge in the graph.*

Theorem 1.5.1 allows for problem reductions for independent set and vertex cover problems.

#### 1.5.3.1 Reduction of the Independent Set and Vertex Cover Problem

There are two problems for the independent set: an optimization problem and a decision problem.

**Problem 1.5.2** (Optimization of an Independent Set in  $G$ ). Given a graph  $G$ , what is the largest independent set in  $G$ ?

**Problem 1.5.3** (Decision of an Independent Set of Size  $k$ ). Given a graph  $G$  and a number  $k$ , does  $G$  contain an independent set of size at least  $k$ ?

An algorithm that solves the optimization problem automatically solves the decision problem of the independent set. An algorithm that solves the decision problem for all size  $k$  solves the optimization problem where the decision is "yes" for the largest value of  $k$ . This establishes a reduction of the optimization problem to the decision problem and vice versa.

### 1.6 Satisfiability

Let  $x_1, \dots, x_n$  be boolean variables. A boolean formula is a combination of conjunction, disjunctions, and negations of the boolean variables  $x_1, \dots, x_n$ . A boolean formula is *satisfiable* if one can assign true or false value to each variable so that the formula is true.

**Problem 1.6.1** (Satisfiability Problem (SAT)). Given a boolean formula, decide whether it is satisfiable.

[?] It is known that every boolean formula can be rewritten in *conjunctive normal form* (CNF), a conjunction of clauses. A *clause* is a disjunction of distinct literals. A *literal* is a variable or a negated variable,  $x_i$  or  $\bar{x}_i$ , for  $i = 1, \dots, n$ . Furthermore, it is also known that every boolean formula can be written in CNF such that each clause has exactly three literals. This form is called 3-CNF. Given a boolean formula in 3-CNF, decide whether it is satisfiable is a *3-SAT problem*.

The problems we focus on in this thesis have a geometry. A special geometric 3-SAT problem is that Planar 3-SAT Problem. Given a 3-CNF boolean formula,  $B$ , we define the associated graph as follows: the

vertices correspond to the variables and clauses in  $B$ , when a variable or its negation appears in a clause there is an edge between the corresponding vertices.

*Problem 1.6.2 (Planar 3-SAT).* Given a boolean formula  $B$  in 3-CNF such that its associated graph is planar, decide whether it is satisfiable is a *3-SAT problem*.

*Problem 1.6.3 (Not All Equal 3 SAT Problem).* Given a boolean formula in 3-CNF, decide whether it is satisfiable so that each clause contains a true and false literal.

3-SAT, PLANAR 3-SAT, NAE3SAT are NP hard [ADD REFERENCE]. THE PROOF FOR THESE REDUCTIONS ARE NOT OBVIOUS BUT ARE SHOWN [HERE, THERE, AND OVER THERE] respectively.

## 1.7 Problem

The *realizability* problem for a polygonal linkage asks whether a given polygonal linkage has a realization (resp., orientated realization). For a weighted planar (resp., plane) graph, it asks whether the graph is the contact graph (resp., ordered contact graph) of some disk arrangement with specified radii. These problems, in general, are known to be NP-hard. Specifically, it is NP-hard to decide whether a given planar (or plane) graph can be embedded in  $\mathbb{R}^2$  with given edge lengths [?, ?]. Since an edge of given length can be modeled by a suitably long and skinny rhombus, the realizability of polygonal linkages is also NP-hard. The recognition of the contact graphs of unit disks in the plane (a.k.a. coin graphs) is NP-hard [?], and so the realizability of weighted graphs as contact graphs of disks is also NP-hard. However, previous reductions crucially rely on configurations with high genus: the planar graphs in [?, ?] and the coin graphs in [?] have many cycles.

In this paper, we consider the above four realizability problems when the union of the polygons (resp., disks) in the desired configuration is simply connected (i.e., contractible). That is, the contact graph of the disks is a tree, or the “hinge graph” of the polygonal linkage is a tree (the vertices in the *hinge graph* are the polygons in PP, and edges represent a hinge between two polygons). Our main result is that realizability remains NP-hard when restricted to simply connected structures.

**Theorem 1.7.1.** *It is NP-complete to decide whether a polygonal linkage whose hinge graph is a tree can be realized (both with and without orientation).*

**Theorem 1.7.2.** *It is NP-complete to decide whether a given tree (resp., plane tree) with positive vertex weights is the contact graph (resp., ordered contact graph) of a disk arrangements with specified radii.*

The unoriented versions, where the underlying graph (hinge graph or contact graph) is a tree can easily be handled with the logic engine method (Section ??). We prove Theorem 1.7.1 for *oriented* realizations with a reduction from PLANAR-3SAT (Section ??), and then reduce the realizability of ordered contact trees to the oriented realization of polygonal linkages by simulating polygons with arrangements of disks (Section ??).

### 1.7.1 Problem Statement

*Problem 1.7.1 (Unordered Realizability Problem for Linkages).* For a linkage, it asks whether its corresponding graph is the contact graph (resp., ordered contact graph) of some disk arrangement with specified radii.

*Problem 1.7.2 (Unordered Realizability Problem for Polygonal Linkages).* The *realizability* problem for a polygonal linkage asks whether a given polygonal linkage has a realization.

*Problem 1.7.3 (Ordered Realizability Problem for Linkages).* For a linkage, it asks whether its corresponding graph is the ordered contact graph of some disk arrangement with specified radii.

*Problem 1.7.4 (Ordered Realizability Problem for Polygonal Linkages).* The *realizability* problem for a ordered polygonal linkage asks whether a given polygonal linkage has a realization with respect to order.

### 1.7.2 Decidability of Problem

test

### 2.0.3 The Logic Engine

Figure 2.1: A logic engine example.

#### 2.0.3.1 Construction of the Logic Engine and Encoding of an NAE3SAT Problem on a Logic Engine

The logic engine is a physical model which can encode instances of the NAE3SAT problem. The components of the logic engine are as follows: the rigid frame, the shaft, the armatures, the chains, and the flags. Suppose we have an NAE3SAT problem,  $P$ , with  $n$  variables and  $m$  clauses. For each variable in  $P$ ,  $v_j$ , there is an *armature*,  $A_j$ . The armatures are placed concentrically within a *rigid frame*. A *shaft* placed at mid-height of the rigid frame and goes through the armatures. The armatures can rotate about the shaft. For each clause  $C_k$  in  $P$ , there are two *links* placed on each armature,  $l_{j,k}$  and  $\bar{l}_{j,k}$ .  $l_{j,k}$  and  $\bar{l}_{j,k}$  place at a height of  $k$  and  $-k$  respectively on each armature. Every link is flagged except in the case of the following two conditions:

1. If the literal  $x_j$  is found in clause  $C_k$ , then  $l_{j,k}$  is unflagged.
2. If the literal  $\bar{x}_j$  is found in clause  $C_k$ , then  $\bar{l}_{j,k}$  is unflagged.

A *collision* of flags occur if either of the following occurs:

1. flags in the same row on adjacent armatures point toward each other.
2. a flag from the outermost armature  $A_n$  points towards the outer rigid frame.
3. a flag from the innermost armature  $A_1$  points inwards of  $A_1$ .

Figure 2.2: (a) Illustrates a type 1 collision, (b) illustrates a type 2 collision, and (c) illustrates a type 3 collision.

**Theorem 2.0.3.** *An instance of NAE3SAT is a “yes” instance if and only if the corresponding logic engine has a flat, collision-free configuration.*

**Proof 2.0.1.** *Suppose there is an instance of an NAE3SAT problem,  $P$ , with  $n$  variables and  $m$  clauses. Let  $t$  be a truth assignment to the literals. If  $t(x_1) = 1$ , rotate the corresponding armature such that  $l_{j,k}$  above the shaft and  $\bar{l}_{j,k}$  below the shaft. If  $t(x_1) = 0$ , rotate the corresponding armature such that  $l_{j,k}$  is below the shaft and  $\bar{l}_{j,k}$  is above the shaft. For each clause  $C_k$  there exists a “true” and “false” literal. For each clause there is a correspond pair of rows accross the armatures. The configuration of those armatures are placed such that there is an unflagged link for at least one “true” and one “false” literal in each row. Configure the flags to point towards the unflagged links. We now have a collision-free configuration.*

*Suppose we have a collision free configuration of a logic engine. We claim that for each row, there exists at least one unflagged armature. To show this, suppose there for any row, there were no unflagged armature. We have two cases:*

1. *Let the flag on  $A_1$  point towards  $A_n$ . Then the flags of  $A_2$  through  $A_{n-1}$  must point towards  $A_n$  to be collision free between  $A_1$  and  $A_{n-1}$ . The flag on  $A_n$  cannot point toward  $A_{n-1}$  otherwise we contradict the hypothesis of the collision free configuration. By definition,  $A_n$  cannot point towards the outer rigid frame, otherwise results into a collision.*

*We’ve shown that there is no collision free row with all armatures flagged in a row. To demonstrate that a collision free configuration exists with one flagless armature, suppose  $A_i$  has a flagless armature. For all  $j$  where  $1 \leq j < i$ , let the flags on  $A_j$  point towards  $A_i$ . For all  $j$  where  $i < j \leq n$ , let the flags on  $A_j$  point towards  $A_i$ . This configuration prevents collision between  $A_k$  and  $A_{k+1}$  for  $k = 1, \dots, n-1$  and without loss of generality there is no collision between  $A_{i-1}$  and  $A_{i+1}$ .*

2. *Let the flag on  $A_n$  point towards  $A_1$ . Then the flags of  $A_2$  through  $A_{n-1}$  must point towards  $A_1$  to be collision free between  $A_2$  and  $A_{n-1}$ . The flag on  $A_1$  cannot point toward outwards to the rigid frame otherwise we contradict the hypothesis of the collision free configuration. By definition,  $A_1$  cannot point inwards, otherwise results into a collision.*

*We’ve shown that there is no collision free row with all armatures flagged in a row. To demonstrate that a collision free configuration exists with one flagless armature, suppose  $A_i$  has a flagless armature.*

Figure 2.3: The blue flags indicate that  $x_j$  or  $\bar{x}_j$  is not found in clause  $C_k$ .

*For all  $j$  where  $1 \leq j < i$ , let the flags on  $A_j$  point towards  $A_i$ . For all  $j$  where  $i < j \leq n$ , let the flags on  $A_j$  point towards  $A_i$ . This configuration prevents collision between  $A_k$  and  $A_{k+1}$  for  $k = 1, \dots, n-1$  and without loss of generality there is no collision between  $A_{i-1}$  and  $A_{i+1}$ .*

*Since there exists at least one unflagged armature in each row, there For flags above the shaft, let each flagged  $l_{j,k}$  indicate that  $x_j$  does not exist in the clause  $C_k$ . For flags below the shaft, let each flagged link indicate that  $\bar{x}_j$  does not exist in the clause. Let  $t$  be a truth assignment to the literals. If  $t(x_1) = 1$ , rotate the corresponding armature such that  $l_{j,k}$  above the shaft and  $\bar{l}_{j,k}$  below the shaft. If  $t(x_1) = 0$ , rotate the corresponding armature such that  $l_{j,k}$  is below the shaft and  $\bar{l}_{j,k}$  is above the shaft. For each clause  $C_k$  there exists a “true” and “false” literal which yields a instance of an NAE3SAT is a yes.*

The encoding of the logic engine allows us to make other assertions on other types of configurations.

## **2.1 Logic Engines Represented as Polygonal Linkages**

**Theorem 2.1.1.** *It is NP-Complete to decide whether a polygonal linkage is whose hinge graph is a tree can be realized*

## **2.2 Logic Engines Represented as Unit Disk Contact Graphs**
