# Chapter 1

## Background

We consider four decision problems surrounding graph theory and geometry. The graph theory based problems involve polygonal linkages and the geometry based problems involve something called a contact graph of disks. In each problem, we decide whether a polygonal linkage or contact graph has a certain realization in the plane.

This thesis first presents preliminary information needed to pose our four problems, then we formally pose each problem and then provide the hardness results in all four cases. We show that all four problems are intractable, or NP hard (see definition below).

### 1.1 Graphs

A *graph* is an ordered pair  $G = (V, E)$  comprising of a set of vertices  $V$  and a set of edges  $E$ . An edge is a two element subset of  $V$ . Note that with this definition of an edge it is not possible to have one element subset of  $V$  as an edge (sometimes referred to as a self-adjacent edge or loop). The *degree* of a vertex  $v$  is the number of edges that  $v$  is an element of. Vertices are said to be *adjacent* if they form an edge in  $E$ . *Neighbors* of a vertex  $v$  are the vertices adjacent to  $v$ . Edges are said to be adjacent if they share a vertex.

A *simple graph* has no self-adjacent vertices. In this thesis every graph is a simple graph. Given a graph  $G = (V, E)$ , a set of vertices  $S \subset V$  is *independent* if no two vertices in  $S$  are joined by an edge. A *vertex cover* of a graph  $G = (V, E)$  is a set of vertices  $S \subset V$  if every edge  $e \in E$ , has at least one end corresponding in  $S$ . If  $G' = (V', E')$  is a graph such that  $V' \subset V$  and  $E' \subset E$ , then  $G'$  is a *subgraph* of  $G$ .

To formally show when two graphs are the same, we use the concept of graph isomorphism. Two graphs  $G_1 = (V_1, E_1)$  and  $G_2 = (V_2, E_2)$  are *isomorphic* if there exists a bijective function  $f : V_1 \mapsto V_2$  such that for any two vertices  $u, v \in V_1$ , we have  $\{u, v\} \in E_1$  if and only if  $\{f(u), f(v)\} \in E_2$ . See an example in Table ?? and Figure 1.21.

Graph	Vertices	Edges
$G_1$	$\{a, b, c, d, e\}$	$\{(a, b), (b, c), (c, d), (d, e), (e, a)\}$
$G_2$	$\{1, 2, 3, 4, 5\}$	$\{(1, 2), (2, 3), (3, 4), (4, 5), (5, 1)\}$

Table 1.1: Two graphs that are isomorphic with the alphabetical isomorphism  $f(a) = 1, f(b) = 2, f(c) = 3, f(d) = 4, f(e) = 5$ .

Figure 1.1: This figure depicts the graph isomorphism shown in Table ?? between  $V_1$  and  $V_2$ .

To visualize a graph,  $G$ , we create a drawing  $\Gamma$ , of  $G$ . The *drawing* of a graph  $G = (V, E)$  is an injective mapping  $\Pi : V \mapsto \mathbb{R}^2$  which maps vertices to distinct points in the plane and for each edge  $\{u, v\} \in E$ , a continuous, injective mapping  $c_{u,v} : [0, 1] \mapsto \mathbb{R}^2$  such that  $c_{u,v}(0) = \Pi(u)$ ,  $c_{u,v}(1) = \Pi(v)$ , and the curve  $c_{u,v}$  does not pass through any other vertex in  $V$ . In this thesis, we will strictly work with straight line drawings where all  $c_{u,v}$  are straight line segments unless specified otherwise. Kuratowski's theorem characterizes finite

Figure 1.2: The  $K_5$  and  $K_{3,3}$  drawn in the plane.

planar graphs. A finite graph is planar if and only if it does not contain a subgraph that is a subdivision of  $K_5$  or  $K_{3,3}$  [15]. Figure 1.2 shows a drawing of  $K_5$  and  $K_{3,3}$ . Two edges in a drawing *cross* if they have a common interior point. The *crossing number* of a graph is the smallest number of edge crossings for a graph over all drawings. A drawing is said to be *planar* if no two distinct edges cross [3]. A planar drawing is also called an *embedding*. Two embeddings of a graph  $G$  are *equivalent* if for every vertex the counter-clockwise order of neighbors are the same. A combinatorial *embedding* is a planar drawing with a corresponding counter-clockwise order of the neighbors of each vertex. An orientation preserving rigid transformation (i.e., rotation

Figure 1.3: Here is a wheel graph,  $W_5$ , in two separate drawings with the same counterclockwise ordering of neighbors for each vertex.

and translation) map an embedding to an equivalent embedding. Reflections reverse the counter-clockwise order around each vertex.

Figure 1.3 depicts two different drawings of the wheel graph  $W_5$ . The drawings have the following counter-clockwise order of neighbors for each vertex: Referencing table ?? and Figure 1.3, we realize that the two drawings of  $W_5$  are equivalent.

Vertex	Left & Middle Drawing	Right Drawing
1	(2, 5, 4)	(4, 5, 2)
2	(3, 5, 1)	(1, 5, 3)
3	(2, 4, 5)	(5, 4, 2)
4	(1, 5, 3)	(3, 5, 1)
5	(2, 3, 4, 1)	(4, 3, 2, 1)

Table 1.2: A table showing the counter-clockwise circular ordering of neighbors for the left and right drawing in Figure 1.3. Note that the permutation cycles are equivalent for the right and left drawings.

### 1.1.1 Trees

A *path* is a sequence of vertices in which every two consecutive vertices are connected by an edge.

Figure 1.4: An embedding of the Petersen graph with a simple cycle of (2,7,9,6,1,0,5,8,3).

A *simple cycle* of a graph is a sequence,  $(v_1, v_2, \dots, v_{t-1}, v_t)$ , of distinct vertices such that every two consecutive vertices are connected by an edge, and the last vertex,  $v_t$ , connects to  $v_1$  (see Figure 1.4). A graph is *connected* if for any two vertices, there exists a path between the two points. A *tree* is a graph that has no simple cycles and is connected (see Figure 1.5). Every tree is planar. A *forest* is a disjoint union of trees.

Figure 1.5: An example of a tree.

An *ordered tree* is a tree  $T$  together with a cyclic order of the neighbors for each vertex (see Figure 1.6).

Figure 1.6: A tree with two embeddings with different cyclic orderings around vertices.

Embeddings of ordered trees are combinatorially equivalent if for each node the counter-clockwise ordering of adjacent nodes are the same.

## 1.2 Linkages

Figure 1.7: Here are skeleton drawings of a human and a turkey. When animating skeletons, one tends to make sure that the lengths of the skeleton segments are kept the same length throughout the animation. Otherwise, the animation may depart from what is ideally understood of skeletal motions.

When graph drawings model physical objects, other qualities about the graph can be contextualized in a geometric sense. Distance, angular relationships and other geometric qualities may be relevant. In any drawing, edges have length, angles formed by adjacent edges, and so on. In this thesis we are interested in the inverse problem where we would like to embed a graph with specific geometric properties, for example, an embedding with specified edge lengths. This motivates the following definition. A *length assignment* of a graph  $G = (V, E)$  is a function  $\ell : E \mapsto \mathbb{R}^+$ . If  $\ell(e)$  is the length of an edge  $e$ ,  $\ell(e)$  must be strictly positive in a drawing, otherwise it may result in two distinct vertices with the same coordinates. Similar to combinatorial embeddings which is an equivalence class of embeddings of the same counter-clockwise order of vertices, we can also define an equivalence class of drawings with the same length assignment. A *linkage* is a graph  $G = (V, E)$  with a length assignment  $\ell : E \mapsto \mathbb{R}^+$  (e.g., see Figure ??).

## 1.3 Polygonal Linkages

A generalization of linkages is a polygonal linkage where edges of given lengths are replaced with rigid polygons. Formally, a *polygonal linkage* is an ordered pair  $(\mathcal{P}, \mathcal{H})$  where  $\mathcal{P}$  is a finite set of polygons and  $\mathcal{H}$  is a finite set of hinges; a *hinge*  $h \in \mathcal{H}$  corresponds to two or more points on the boundary of distinct polygons in  $\mathcal{P}$ . A *realization* of a polygonal linkage is an interior-disjoint placement of congruent copies of the polygons in  $\mathcal{P}$  such that the copies of a hinge are mapped to the same point (e.g., Figure

1.8). A realization of a polygonal linkage with fixed orientation is a realization in which each polygon is

Figure 1.8: (a) A polygonal linkage with a non-convex polygon and two hinge points corresponding to three polygons. Note that hinge points correspond to two distinct polygons.(b) Illustrating that two hinge points can correspond to the same boundary point of a polygon.

translated and rotated copy of a polygon in  $\mathcal{P}$ ; at each hinge the incident polygons are in a given counter-clockwise order (refer to Figure ??). Note that oriented polygonal linkage realizations do not allow for

Figure 1.9: Two realizations of the same polygonal linkage with that differ in the counter-clockwise order of polygons around vertex  $a$ .

reflection transformations of polygons in  $\mathcal{P}$ .

These two realization types allow one to pose two different problems, the realizability problem for polygonal linkages and the realizability problem for polygonal linkages with fixed orientation:

**Problem 1** (Realizability Problem for Polygonal Linkages). Given a polygonal linkage, does it have a realization?

**Problem 2** (Realizability Problem for Polygonal Linkages with Fixed Orientation). Given a polygonal linkage with fixed orientation, does it have a realization?

Not every polygonal linkage has a realization. Consider the 7 congruent copies of an equilateral triangle with a common hinge point in Figure 1.10. To show it does not have a realization, suppose it is realizable. Each angle of every triangle is  $\frac{\pi}{3}$  radians. The sum of 7 angles formed by the triangles is  $\frac{7\pi}{3} > 2\pi$ . The total radian measure around  $A$  is  $2\pi$ . The contradiction is that the sum of 7 angles formed by the triangles in an interior disjoint placement is  $\frac{7\pi}{3}$ . The polygonal linkage of Figure 1.10 would overlap itself and does not have a realization.

There are polygonal linkages that admit realizations but every realization requires rotation. Figure ?? show the congruent copies of the polygons  $A$ ,  $B$ ,  $C$ , and  $D$  in two different configurations, the far right is a realization, the middle fails to be a realization because of the interiors of  $B$  and  $D$  intersecting and the left

Figure 1.10: Here we have 7 congruent copies of an equilateral triangle with a hinge point of  $A$ . The polygonal linkage is not realizable. The best we can realize is at most 6 congruent copies of an equilateral triangle with the hinge point of  $A$  in the plane.

showing the polygons in  $\mathcal{P}$ . In fact, this polygonal linkage cannot admit a realization with fixed orientation. Indeed this polygonal linkage cannot satisfy Problem 2, suppose there is a realization with fixed orientation. Without loss of generality, fix the placement of  $C$ .  $A$ ,  $B$ , and  $D$  have unique placement around triangle  $C$ . In this placement  $C$  and  $D$  overlap. Figure ??, satisfies Problem 1 but not Problem 2. The far right is a realization

Figure 1.11: This example shows yet another example where two realizations of the same polygonal linkage. One realization where there is an intersection and another where there isn't an intersection.

but with polygon  $B$  reflected.

Figure ?? does not quite get at the heart of the challenge with Problem 1 because the counter-clockwise order of the polygons around hinges is not considered.

Figure 1.12: Here we have two realizations of a polygonal linkage with two different counter-clockwise order  $(C,B,A)$  and  $(B,C,A)$  respectively. Note that the placement with ordering  $(B,C,A)$  has an overlap.

Figure ?? shows three polygons with a common hinge. In the counter-clockwise order  $(A,B,C)$ , the polygonal linkage admits a realization whereas in the counter-clockwise order  $(A,C,B)$ , it does not admit a realization. The examples above show that answers to Problem 1 and 2 could be yes or no; the answer could be negative for various reasons. Sections 2 and 3 of this thesis address the computational complexity of solving Problems 1 and 2. We show that both problems are intractable.

### 1.3.1 Geometric Dissections

Hilbert's third problem asks: given any two polyhedra of equal volume, is it always possible to cut the first into finitely many polyhedral pieces which can be reassembled to yield the second [2]? In three dimensions the answer is no however for two dimensions it is true [22].

The Wallace-Bolyai-Gerwien Theorem simply states that two polygons are congruent by dissection iff they have the same area. A *dissection* being a collection of smaller polygons whose interior disjoint union forms a polygon. Hinged dissections of a polygon  $P$  is a polygonal linkage that admits a realization that forms  $P$ . Demaine et. al. [1] showed that any two polygons of the same area have a common hinged dissection where polygonal pieces must hinge together at vertices to form a connected realization and that there exists a continuous motion between the two realizations (refer to section 1.5.3). This was an outstanding problem for many years until 2007.

The Haberdasher Puzzle was proposed in 1902 by Henry Dudeney: can a square and an equilateral triangle of the same area have a common dissection into four pieces?

Figure 1.13: The Haberdasher Puzzle was proposed in 1902 and solved in 1903 by Henry Dudeney. The dissection is for polygons that forms a square and equilateral triangle

Figure 1.14: Two configurations of polygonal linkage where the polygons touch on boundary segments instead of hinges. These two realizations of the polygonal linkage are invalid to our definitions.

Geometric dissections are closely related to polygonal linkages. Figure 1.14 shows two arrangements of the same polygons to form a hexagon and a square. The polygons are not hinged and are arranged in differing order. The polygons are merely tiled together to form the hexagon and square. Figure 1.15, shows the Haberdasher problem with hinges. This makes the Haberdasher problem as a type of polygonal linkage where the polygons are free to move about their hinge points and take the form of a triangle or square.

Figure 1.15: This shows the Haberdasher problem in the form of polygonal linkage [1]. This is a classic example of two polygons of equal area that have a common hinged dissection.

## 1.4 Disk Arrangements

A *disk arrangement* is a set of interior disjoint disks,  $D$ . If for any pair of disks in  $D$  intersect at a boundary point, they are said to be in contact (kissing). A *contact graph*  $G = (V, E)$  corresponding to a given

Figure 1.16: This example represents a disk arrangement and its contact graph.

disk arrangement where there is a bijection  $b_V : V \mapsto D$  and a bijection that maps an edge  $e_{i,j} \in E$  to an interior disjoint pair of disks  $d_i, d_j \in D$  (see Figure 1.16). Given a disk arrangement, the contact graph can be thought of as a linkage because the distance between two kissing disk equal the sum of radii. However if the two disks don't kiss, the distance between their centers is strictly greater than the sum of their radii. Given a

disk arrangement, the contact graph can be thought of as a linkage because the distance between two kissing disk equal the sum of radii. However if the two disks don't kiss, the distance between their centers is strictly greater than the sum of their radii.

Koebe's theorem states that for every planar graph  $G$ , there exists a planar disk arrangement whose contact graph is  $G$  [14]. This motivates the question of whether a planar graph  $G$  is a contact graph of a disk arrangement with given radii. The radii can be given by a weight function. Let  $\omega : V \mapsto \mathbb{R}^+$  be the *weight function*.  $\omega$  assigns a weight to each vertex in  $V$ . Let  $\Pi : V \mapsto \mathbb{R}^2$  be that planar mapping of vertices.

For planar graphs with positive weighted vertices, we pose two realizability problems:

**Problem 3** (Unordered Realizability Problem for a Contact Graph). Given a planar graph with positive weighted vertices, is it a contact graph of some disk arrangement where the radii equal the vertex weights?

**Problem 4** (Ordered Realizability Problem for a Contact Graph). Given a planar graph with positive weighted vertices and a combinatorial embedding, is it a contact graph of some disk arrangement where the radii equal the vertex weights and the counter-clockwise order of neighbors of each disk is specified by the combinatorial embedding?

An instance of Problem 3 is shown in Figure 1.16 where the cycle graph  $C_5$  is the contact graph of unit disks. It is not difficult to see that there exists a planar graph with positive weights with no realizable disk arrangement. Consider the a star graph with 6 leafs, each vertex with unit weight. In any realization, the angle between two consecutive edges must be greater than  $\frac{\pi}{3}$ . The sum of 6 angles is  $2\pi$  however, the sum of 6 consecutive angles is greater than  $2\pi$ . The contradiction shows that no realization is possible (refer to Figure ??). Note that with the wheel graph  $W_7$  is realizable as a contact graph of unit disks.

Every path with arbitrary positive radii is realizable as a contact graph, place the vertices on a line. We show that not all binary trees are realizable, even with unit disks. Consider the balanced binary trees of depth  $i$   $\{T_i\}_{i=1}^{\infty}$  with unit weights on the vertices (see Figure 1.18). These trees are not realizable for sufficiently large  $i$ . Let  $i$  be a positive integer and suppose that  $T_i$  is a contact graph of unit disks. The balanced binary

Figure 1.17: We show the linkages  $T_2$  through  $T_5$  with distance 2 between adjacent vertices.

tree  $T_i$  has  $2^i - 1$  vertices. The total area of the disks is  $(2^i - 1)^2 \cdot \pi$ . We now derive an upper bound for this area. Suppose the disk corresponding to the root of the tree is centered at the origin. The centers of the disks at level  $j$  are at a distance at most  $2 \cdot (j - 1)$  away from the origin. The centers of all disks are at distance at most  $2 \cdot (i - 1)$  away from the origin. All unit disks are contained in a disk of radius  $2i - 1$  centered at the origin. The total area of the disks is at most  $(2i - 1)^2 \cdot \pi$ . A upper bound of the total area of the disk arrangement is the area of the bounding box of the disks. The upper bound of the

Figure ?? shows the first four non-trivial trees as a contact graph of unit disks. Every disk at level up to  $i$  is contained in a disk of radius  $2 \cdot i - 1$  centered at the origin. The total area of the disk arrangement is  $(2 \cdot i - 1)^2 \cdot \pi$ . When  $i \geq 8$  we have a contradicton.

There are instances where a planar graph with weights admits a realization but the cyclic order of neighbors may not be the same as the combinatorial embedding. Define  $G$  as follows: start with a star centered

Figure 1.18: For  $i = 2, 3, 4, 5$  the tree  $T_i$  is a contact graph of unit disks.

Figure 1.19: Consider these two ordered disk arrangements where A and B are in the concentric rings of disks. The large disks are in contact to A and B respectively. If A and B are adjacent, then there is a restriction of how large the size of the disks can be that are attached to them as seen in on the left. Whereas if A and B are not adjacent in this disk arrangement as shown on the right, the size of the kissing disks could be arbitrarily large.

at  $C$  and with 6 leafs,  $A_1$  through  $A_6$ ; attach two leafs,  $B_1$  and  $B_2$ , to  $A_1$  and  $A_2$  respectively (see Figure ??). Let the weight of  $C$  be  $1 + \varepsilon$  for sufficiently small  $\varepsilon > 0$ . The neighbors of  $C$  have unit weight. The weights of the two leafs have weight  $\frac{1}{\varepsilon}$ . The right of Figure ?? shows a realization where  $A_1$  and  $A_2$  are in opposite position of the counter-clockwise order around  $C$ . If  $A_1$  and  $A_2$  are required to be consecutive in the counter-clockwise order around  $C$ , there is no realization.

Suppose there is a realization where  $A_1, \dots, A_6$  are in the counter-clockwise order around  $C$  (see Figure ??). If  $\varepsilon > 0$  is sufficiently small, then the centers of  $A_1, \dots, A_6$  are arbitrarily close to the vertices of a regular hexagon. Consider the common tangent lines between  $A_1$  and  $B_1$  and  $A_2$  and  $B_2$ . The possible position of tangent line between  $A_1$  and  $B_1$  ranges from the common tangent line of  $A_1$  and  $A_6$  to the common tangent line of  $A_1$  and  $A_2$ . Similarly, The possible position of tangent line between  $A_2$  and  $B_2$  ranges from the common tangent line of  $A_2$  and  $A_3$  to the common tangent line of  $A_1$  and  $A_2$ . In any position, the common tangent lines between  $A_1$  and  $B_1$  and  $A_2$  and  $B_2$  intersect. If  $\frac{1}{\varepsilon}$  is sufficiently large, then the disks  $D_1$  and  $D_2$  also intersect. This contradicts that there is a realization. Figure ?? shows how an ordered contact graph may

Figure 1.20: This example represents a disk arrangement and its contact graph.

not be realizable. On the left, it shows a limitation on the weights of the disks that are in contact with disks  $A$  and  $B$ . On the right, the figure shows the order where  $A$  and  $B$  are on opposing ends of the ring of disks and can allow of arbitrary size of weighted disks in contact with  $A$  and  $B$ .

## 1.5 Configuration Spaces

Just as one can compose colors or forms, so one can compose motions.

Alexander Calder, 1933

Recall Figure 1.15 illustrating the hinged dissection that formed a square and triangle and several drawings of the hinged dissections that simulate the motion of moving the polygons around the hinge points to form each shape. The set of all drawings in that motion represents the *configuration space* for that polygonal linkage. In this section we will formally describe the configuration space for each object we've drawn thus far.

### 1.5.1 Configuration Spaces of Graph Drawings

Recall that for a graph drawing we have an injective mapping  $\Pi : V \mapsto \mathbb{R}^2$  which maps vertices to distinct points in the plane and for each edge  $\{u, v\} \in E$ , a straight line segment,  $c_{u,v} : [0, 1] \mapsto \mathbb{R}^2$  such that  $c_{u,v}(0) = \Pi(u)$  and  $c_{u,v}(1) = \Pi(v)$ , and does not pass through other vertices. For each vertex of  $G$ , the embedding of the vertex lies in the plane, i.e.  $\Pi(v) \in \mathbb{R}^2$ . By enumerating each vertex of  $G$ , e.g.  $v_1, v_2, \dots, v_k, \dots, v_n$ , we can create a projection mapping from  $\mu : \Pi \mapsto \mathbb{R}^{2|V|}$  where the corresponding coordinates of  $\Pi(v_k)$  are in the  $(2k)^{\text{th}}$  and  $(2k+1)^{\text{th}}$  coordinates in  $\mathbb{R}^{2|V|}$ .  $\mu(\Pi)$  is a configuration. The configuration space is the set of  $\mu(\Pi)$  for all drawings  $\Pi$ .

### 1.5.2 Configuration Spaces of Linkages

Consider drawings of a graph that respects the length assignment. A *realization* of a linkage,  $(G, \ell)$ , is a drawing of a graph,  $\Pi$ , such that for every edge  $\{u, v\} \in E$ ,  $\ell(\{u, v\}) = |\Pi(u) - \Pi(v)| = |\Pi(v) - \Pi(u)|$ . A *plane realization* is a plane drawing with the property,  $\ell(\{u, v\}) = |\Pi(u) - \Pi(v)|$ . First let's define the space of realizations for a corresponding linkage, i.e.:

$$P_{(G, \ell)} = \{ \Pi_{(G, \ell)} \mid \forall \{u, v\} \in E, \ell(\{u, v\}) = |\Pi(u) - \Pi(v)| \}$$

With respect to  $P$ , we can establish a *configuration space* that allows one to study problems of motion. For each vertex of  $G$ , the drawing of the vertex lies in the plane, i.e.  $\Pi(v) \in \mathbb{R}^2$ . By enumerating each vertex of  $G$ , e.g.  $v_1, v_2, \dots, v_k, \dots, v_n$ , we can create a projection mapping from  $\mu : P \mapsto \mathbb{R}^{2|V|}$  where the corresponding coordinates of  $\Pi(v_k)$  are in the  $(2k)^{\text{th}}$  and  $(2k+1)^{\text{th}}$  coordinates in  $\mathbb{R}^{2|V|}$ . The configuration space is  $\mu(P)$ .

Using standard definitions from real analysis, we can begin to pose problems about linkages with respect to a corresponding configuration space. We define a path  $\gamma : [0, 1] \mapsto \mu(P)$  where  $\gamma(0)$  corresponds the the projection of a realization of a linkage  $\Pi_0$  and  $\gamma(1)$  corresponds to another realization of a linkage  $\Pi_1$ . If for any two elements  $a, b \in \mu(P)$  that there exists a continuous path  $\gamma$  such that  $\gamma(0) = a$  and  $\gamma(1) = b$ ,  $\mu(P)$  is said to be path connected. For  $\gamma$  to be continuous we would have that for every  $\varepsilon > 0$ , there exists a  $\delta > 0$  such that if  $x, y \in [0, 1]$  and  $|x - y| < \delta$  then  $\|\gamma(x) - \gamma(y)\| < \varepsilon$ .  $\gamma$  can be thought of as an animation of drawings that starts at  $\gamma(0)$  and ends at  $\gamma(1)$ . To ask if  $\mu(P)$  is a connected space, is to ask if  $\mu(P)$  is connected in  $\mathbb{R}^{2|V|}$ . The Carpenter's Rule states that every realization of a path linkage can be continuously moved (without self-intersection) to any other realization [8, 21]. In other words, the realization space of such a linkage is always connected.

Figure 1.21: (a) and (b) show a linkage in two embeddings. Any realization of a path can be continuously moved without self-intersection to any other realizations.

### 1.5.3 Configuration Spaces of Polygonal Linkages

Recall a realization of a polygonal linkage is an interior-disjoint placement of congruent copies of the polygons in  $\mathcal{P}$  such that the copies of a hinge are mapped to the same point (e.g., Figure 1.8). First consider the set of all realizations for the polygonal linkage.  $(\mathcal{P}, \mathcal{H})$  and call it  $P$ . For any realization  $R \in P$ , the parameterization  $\mu : R \mapsto \mathbb{R}^{2m}$  where  $m$  is the number of distinct vertices in  $\mathcal{P}$ . The configuration space is the set  $\mu(P)$ .

### 1.5.4 Configuration Spaces of Disk Arrangements

Figure 1.22: An example of a disk arrangement where  $A$  and  $B$  have a large range of freedom to move around.  $C, D, E$ , and  $F$  are limited in their range of motion due to their hinge points.

Consider the set of realizations  $P$  for a given disk arrangement  $\mathcal{D} = \{D_i\}_{i=1}^n$ . For any realization  $R \in P$ , there exists a corresponding contact graph,  $C$ . The configuration spaces of  $\mathcal{D}$  are sets of  $R \in P$  that are classified by the equivalent contact graphs, i.e. if  $R_1, R_2 \in P$  and their corresponding contact graphs  $C_1$  and  $C_2$  have a graph isomorphism,  $\phi$ , then  $R_1$  and  $R_2$  belong to the same configuration space.

## 1.6 Algorithm Complexity

*Algorithms* are a list of instructions executed with a given input. The efficiency of an algorithm can be measured in terms of the amount of resources it uses such as time, memory, and power. Ideally, a desirable algorithm would primarily have a small run time and secondarily utilize a small amount of resources.

The time and space used by an algorithm is measured with units defined by a model of computation. The actual running time of an algorithm depend on a variety of factors for example: the processor, the hardware, the temperature, etc. Mathematical models of computation have been developed to measure running time of algorithms independent of the machine it runs on. One of the oldest and most popular models is the random access machine (RAM) model. RAM measures the unit of space in the number of words used where each word can store an arbitrary integer. In the real RAM, each word can store an arbitrary real number. The units of time is measured in the number of arithmetic operations and number of memory accesses (read or write).

The *running time* of an algorithm on a given input, is the time it takes to terminate. The *worst-case* running time is the largest running time over all inputs of a given size  $N$ . It is a function of  $N$ , it is usually monotonically increasing function since larger inputs tend to take more time to process. The key parameter of the efficiency of an algorithm is the growth rate of its worst case running time in terms of  $N$ . An algorithm is said to be *efficient* if the time needed to perform the list of instructions can be determined from a polynomial. Devising an efficient algorithm for a given problem is often a difficult task.

The growth rate of running times are typically compared upto constant vectors. Let  $f$  and  $g$  be defined on some subset of  $\mathbb{R}$ .  $f(x) = O(g(x))$  if and only if there exists a constant  $M$  and  $x_0$  such that

$$|g(x)| \leq M|f(x)|$$

for all  $x \geq x_0$

### 1.6.1 Complexity Classes

Problems can be categorized by their running times. Each algorithm computes a function  $f(I)$  on an input  $I$ , however many different algorithms can compute the same function. Algorithms are differentiated by their running times but the function is characterized by the fastest algorithm that can compute it. A problem can be formulated as follows, given input  $I$  find  $f(I)$ .

Problems can be categorized into complexity classes based on the fastest algorithms that solve them. The class of problems that can be solved in polynomial running time is called the *polynomial time* class, P.

A second property of problems is whether its solution can be verified efficiently. This property is independent of whether it can be solved efficiently.  $B$  is said to be an *efficient certifier* for a problem  $X$  if the following properties hold:

- (i)  $B$  is a polynomial-time algorithm that takes two inputs  $s$  and  $t$ .
- (ii) There exists a polynomial function  $p$  such that for every string  $s$ , we have  $s \in X$  if and only if there exists a string  $t$  such that  $|t| \leq p(|s|)$  and  $B(s, t) = \text{'yes'}$ .

The class of problems which have an efficient certifier is said to be the *nondeterministic polynomial time* class, NP. We continue with the definitions for NP-hard and NP-complete. A problem is NP-hard if every problem in NP can be reduced to it in polynomial time. A *polynomial time reduction* is when arbitrary instances of problem  $Y$  be solved using a polynomial number of standard computational steps, plus a polynomial number of calls to a black box that solves problem  $X$ , i.e.  $Y$  is reduced in polynomial time to  $X$ . A problem is NP-complete if it NP and NP-hard, i.e. NP-complete = NP  $\cap$  NP-hard.

### 1.6.2 RSA Cryptosystem

Cryptography is the study of secure communication between parties in an untrusted or unsecure communication channel. Cryptography has three primary purposes for secure communications: provide confidentiality, authenticate entities, and verification of data. Modern cryptography is based on hard math problems such as integer factorization, discrete logarithmic problem, and pre-image problems. Hard math problems are not found in P and found in NP. In most forms of modern cryptography, *keys*, are data parameters used to form function outputs for the use in a communication channel. There are three common types of keys in cryptography:

1. A *secret key* is known by certain entities. Typically a secret key is used by entities to encrypt and decrypt data that is communicated over an untrusted channel. Secret keys require a secure channel to exchange between all entities.
2. When there are no means to exchange secret keys, one can use a private and public key scheme. A *public key* is a key that can be shared with any entity, i.e. trusted and untrusted entities can know it. The *private key* is a key that is kept to one entity. It is treated like a secret key and should only be known to that entity.

A *cryptosystem* is a suite of algorithms used to establish secure communication channel between parties. The RSA cryptosystem is the first practical cryptosystem in modern cryptography that allows for encryption of

data (confidentiality), authentication of entites, and verify message integrity using just one underlying hard math problem, integer factorization.

RSA is named after its second inventors, Ron Rivest, Adi Shamir, and Leonard Adelman. These three individuals devised and published the algorithm in 1977. The original inventor of RSA was Clifford Cocks in 1973 however, it was only known to the public since 1997 that Clifford Cocks was the original inventor because his was was classified by Government Communication Headquarters, an intelligence agency of the United Kingdom.

For the RSA cryptosystem, we first want to pose the communication security problem. Suppose we have two entities, Alice and Bob, that wish to communicate over an unsecure channel. Should Alice and Bob agree to using RSA, each entity will have a pair of keys, a private key and a public key. Most implementations of RSA use the following key derivation [19]:

1. Let  $n = p \cdot q$  where  $p$  and  $q$  are randomly chosen prime numbers.
2. Choose an integer  $e$  such that  $1 < e \leq \phi(n)$  and  $\gcd(e, \phi(n)) = 1$  where  $\phi$  is the Euler totient function.
3. Let  $d \equiv e^{-1} \pmod{\phi(n)}$ .

The RSA cryptosystem is based around the following formula:

$$(m^e)^d \pmod n = (m^d)^e \pmod n \equiv m \pmod n$$

where we have natural numbers  $e, d, m$ , and  $n$ , such that  $m < n$  and  $\gcd(m, n) = 1$ .

If Alice derives a public and private key in the manner described, her public key is  $(n, e)$  and her private key is  $d$ . Suppose Bob wants to send Alice a message  $M$ . Bob will represent  $M$  in binary form,  $m$ . Alice sends her public key  $(n, e)$  to Bob and keeps her private key  $d$  secret. If  $\gcd(m, n) \neq 1$ , then Bob modifies  $m$  by padding  $m$  with additional digits so that  $m$  becomes co-prime with  $n$ . There are efficient padding schemes to modify  $m$  such that  $m$  and  $n$  are co-prime [11]. Bob sends the following value,  $c$ , to Alice:

$$c \equiv m^e \pmod n$$

$c$  is said to be a ciphertext. Alice can decrypt the ciphertext and recover  $m$  by computing:

$$m \equiv c^d \pmod n = (m^e)^d \pmod n$$

The RSA cryptosystem is based on integer factorization and the RSA problem, given  $n$  where  $n = p \cdot q$  where  $p$  and  $q$  are prime numbers, find  $p$  and  $q$ . For sufficiently large integers, factorization and the RSA problem becomes very difficult. If there were an algorithm that solved integer factorization in polynomial time, then one can also solve the RSA problem as well. Suppose a third party listens into the conversation and knows Alice's public key  $(n, e)$  and the ciphertext  $c$ . If the the third party can factor  $n = p \cdot q$  then the attacker can computer  $\phi(n)$  and compute  $d \equiv e^{-1} \pmod{\phi(n)}$  using the extended euclidian algorithm. Once they have  $d$ , the attacker can compute  $m \equiv c^d \pmod n$ .

Currently, the most efficient factorization algorithm is the general number sieve algorithm [16]. It's an exponential running time algorithm. If a polynomial running time algorithm for integer factorization existed, it would allow for compromise of security that is provided to communicating parties by the RSA cryptosystem. It would allow for a reduction of the integer factorization problem, a problem that exists in NP but not P. The algorithm would allow for an adversary to attack RSA [18] in polynomial time.

## 1.7 Satisfiability

Let  $x_1, \dots, x_n$  be boolean variables. A boolean formula is a combination of conjunction, disjunctions, and negations of the boolean variables  $x_1, \dots, x_n$ . A *clause* is a disjunction of distinct literals. A *literal* is a variable or a negated variable,  $x_i$  or  $\bar{x}_i$ , for  $i = 1, \dots, n$ . A boolean formula is *satisfiable* if one can assign true or false value to each variable so that the formula is true. It is known that every boolean formula can be rewritten in *conjunctive normal form* (CNF), a conjunction of clauses, via DeMorgan's law and distributive law. Furthermore, it is also known that every boolean formula can be written in CNF such that each clause has exactly three literals. This form is called 3-CNF. For example, consider the clause  $A \vee B \vee C \vee D \vee E$ . This clause can be rewritten in 3-CNF form as  $(A \vee B \vee x_1) \wedge (\neg x_1 \vee C \vee x_2) \wedge (\neg x_2 \vee D \vee E)$  where  $x_1$  and  $x_2$  are literals that allow us to form 3-CNF clauses. Here are the problem statements for satisfiability:

**Problem 5** (Satisfiability Problem (SAT)). Given a boolean formula, is it satisfiable? [20]

*Brute force* is when an algorithm tries all possibilities to see if any formulates a satisfiable solution. It is clear that SAT is decidable in exponential time by testing all possibilities. This is called a brute force solution. It is not known whether SAT admits a polynomial time solution, that is whether it is in P.

**Problem 6** (3-SAT Problem). Given a boolean formula in 3-CNF, is it satisfiable?

The problems we focus on in this thesis have a geometry. A special geometric 3-SAT problem is that Planar 3-SAT Problem. Given a 3-CNF boolean formula,  $\Phi$ , with  $n$  variables and  $m$  clauses. We define the *associated graph*  $A(\Phi)$  as follows: the vertices correspond to the variables and clauses in  $\Phi$ . We place an edge in the graph if variable  $x_i$  appears in clause  $C_j$ .

Figure 1.23: Left: the associated graph  $A(\Phi)$  for a Boolean formula  $\Phi$ . Right: the schematic layout of the variable, clause, and transmitter gadgets in the auxiliary construction showing in Section 3.1

**Problem 7** (Planar 3-SAT). Given a boolean formula  $\Phi$  in 3-CNF such that its associated graph is planar, decide whether it is satisfiable is a *3-SAT problem*.

Figure 1.23 is associated to a family of boolean formulas. One such associated boolean formula is:

$$(x_1 \vee x_3 \vee \neg x_5) \wedge (\neg x_1 \vee \neg x_2 \vee x_3) \wedge (\neg x_3 \vee x_4 \vee \neg x_5) \wedge (x_2 \vee x_4 \vee \neg x_5) \wedge (\neg x_1 \vee x_2 \vee x_5)$$

Note that the figure establishes an edge relation between variables and clauses whereas the clauses in boolean formulas do not have variables but literals of variables.

**Problem 8** (Not All Equal 3 SAT Problem (NAE3SAT)). Given a boolean formula in 3-CNF, is it satisfiable so that each clause contains a true and a false literal?

Problems 5—8 are known to be NP-hard and are often used to show other problems are NP-hard as well [17, 12].

## 1.8 Contribution

The *realizability* problem for a polygonal linkage asks whether a given polygonal linkage has a realization (resp., orientated realization). For a weighted planar (resp., plane) graph, it asks whether the graph is the contact graph (resp., ordered contact graph) of some disk arrangement with specified radii. These problems,

in general, are known to be NP-hard. Specifically, it is NP-hard to decide whether a given planar (or plane) graph can be embedded in  $\mathbb{R}^2$  with given edge lengths [7, 9]. Since an edge of given length can be modeled by a suitably long and skinny rhombus, the realizability of polygonal linkages is also NP-hard. The recognition of the contact graphs of unit disks in the plane (a.k.a. coin graphs) is NP-hard [6], and so the realizability of weighted graphs as contact graphs of disks is also NP-hard. However, previous reductions crucially rely on configurations with high genus: the planar graphs in [7, 9] and the coin graphs in [6] have many cycles.

In this thesis, we consider the above four realizability problems when the union of the polygons (resp., disks) in the desired configuration is simply connected (i.e., contractible). That is, the contact graph of the disks is a tree, or the “hinge graph” of the polygonal linkage is a tree (the vertices in the *hinge graph* are the polygons in  $\mathcal{P}$ , and edges represent a hinge between two polygons). Our main result is that realizability remains NP-hard when restricted to simply connected structures.

**Theorem 1.** *It is strongly NP-hard to decide whether a polygonal linkage whose hinge graph is a **tree** can be realized.*

**Theorem 2.** *It is strongly NP-hard to decide whether a polygonal linkage whose hinge graph is a **tree** can be realized with fixed orientation.*

Our proof for Theorem 2 is a reduction from PLANAR-3-SAT (P3SAT): decide whether a given Boolean formula in 3-CNF with a planar associated graph is satisfiable. Our proof for Theorem 8 is a reduction from NOT-ALL-EQUAL-3-SAT (NAE3SAT): decide whether a given Boolean formula in 3-CNF is it satisfiable so that each clause contains a true and a false literal?

**Theorem 3.** *It is NP-Hard to decide whether a polygonal linkage whose hinge graph is a tree can be realized (both with and without orientation).*

**Theorem 4.** *It is NP-Hard to decide whether a given tree (resp., plane tree) with positive vertex weights is the contact graph (resp., contact graph) of a disk arrangements with specified radii.*

The unoriented versions, where the underlying graph (hinge graph or contact graph) is a tree can easily be handled with the logic engine method (Section ??). We prove Theorem 3 for *oriented* realizations with a reduction from PLANAR-3SAT (Section ??), and then reduce the realizability of ordered contact trees to the oriented realization of polygonal linkages by simulating polygons with arrangements of disks (Section 1.4).

## 1.9 Related Work and Results

Boris Klemz’s Master’s thesis “Weighted Disk Contact Graph” shows the Unit Disk Touching Graph Recognition problem is NP-Hard. It also improves the Breu and Kirkpatrick result on Disk Touching Graph Recognition problem [13, 6].

## Chapter 2

### Decision Problems for Hinged Polygons and Disks

#### 2.1 The Logic Engine

The *logic engine* is a planar, mechanical device that simulates an instance NAE3SAT problem. It was introduced in Bhatt et. al. [4].

##### 2.1.1 Construction of the Logic Engine

Figure 2.1: A logic engine frame with vertical armatures and a horizontal shaft.

For a given a boolean formula,  $\Phi$ , in 3-CNF with  $n$  variables and  $m$  clauses, we construct a logic engine. The logic engine has a *rigid frame* which houses the mechanical components of the the logic engine. The rigid frame is the boundary of which the logic engine can operate within. The *shaft* is a horizontal line segment that is placed at mid-height of the rigid frame. The *armatures* are vertical line segments whose midpoints are on the shaft. Each armature has two orientations with respect to the shaft. There will be some flags on each armature that will be described later. The armatures each have length  $2n$  units, the shaft has length  $m$  units, and the frame has a height of  $2n$  and width of  $m$  units.

Each armature corresponds to a variable in  $\Phi$ . There are two literals for each variable, i.e. the literal  $x_j$  and the negated literal  $\bar{x}_j$ . To describe the flagging arrangement, first partition each armature into  $2m$  units, vertical line segments. Label the segments on the  $j^{\text{th}}$  armature starting from the shaft by  $\ell_{j,1}, \dots, \ell_{j,n}$  on one side and  $\bar{\ell}_{j,1}, \dots, \bar{\ell}_{j,n}$  on the other side of the shaft. Attach regular triangles, called *flags*, to some of these segments. Each segment is either flagged one or zero flags, i.e. *flagged* or *unflagged*. If the literal  $x_j$  is found in clause  $C_k$ , then  $\ell_{j,k}$  is unflagged. If the literal  $\bar{x}_j$  is found in clause  $C_k$ , then  $\bar{\ell}_{j,k}$  is unflagged.

Figure 2.2: A logic engine that corresponds to a boolean formula in NAE3SAT form,  $\Phi$ . The picture shows the outer rigid frame, the shaft, the armatures that correspond to the variables in  $\Phi$ , with oriented flags.

Each flag has two orientations with respect to armature it is attached to. Each flag has four potential positions, the flag can reflect left or right about the armature and the armature can reflect up or down about the shaft. The *flags* are equilateral triangles attached to the armatures. The placement of the flags is dependent

Figure 2.3: A logic engine constructed from the boolean formula  $\Phi = C_1 \cap C_2 \cap C_3$ .

on the instance of the NAE3SAT boolean formula. Each flag as two orientations.

For the NP hardness reduction in Theorem 6 we need to make sure that all parameters in the logic engine can be specified polynomially in terms of the size of the boolean formula. Given  $\Phi$ , the corresponding logic engine is constructed as follows: all components will be specified with a quantity and coordinates defined as polynomials in  $m$  and  $n$ .

Component	Quantity	Set Definition
Rigid Frame	1	$\{ (x,y) \in \mathbb{R}^2 \mid \text{The boundary of } [\frac{1}{2}, n + \frac{1}{2}] \times [-m, m] \}$
Shaft	1	$\{ (x,y) \in \mathbb{R}^2 \mid x \in [\frac{1}{2}, n + \frac{1}{2}] \text{ and } y = 0 \}$
Armatures	n	For the $j^{\text{th}}$ armature we have $\{ (x,y) \in \mathbb{R}^2 \mid x = j \text{ and } y \in [-m, m] \}$
Flags	$2mn - 3m$	if $\ell_{j,k}$ is flagged then the attached flag is a regular triangle with side length 1.

Table 2.1: The quantity and coordinates of the logic engine components.

### 2.1.2 The mechanics of the logic engine

In any of the following cases, a *collision* of flags occurs:

1. flags in the same row on adjacent armatures point toward each other.
2. a flag from the rightmost armature  $A_n$  points towards the outer rigid frame.
3. a flag from the leftmost armature  $A_1$  points inwards of  $A_1$ .

Figure 2.4: (a) Illustrates a adjacent flag collision at the same height, (b) and (c) illustrates a rigid frame collision.

The logic engine representation corresponding to  $\Phi$  is to be configured such that no horizontally adjacent flags collide and flags do not collide with the rigid frame.

Figure 2.5: The following configuration of adjacent flags and flags that are adjacent to the rigid frame.

**Lemma 1.** *A row has a collision-free configuration if and only if it has at least one unflagged armature.*

*Proof.* Suppose all armatures are flagged in a row. The flag on armature  $A_1$  must point to the right otherwise we result in a rigid frame collision.  $A_2$  must point to the right otherwise we result in a rigid frame collision. Without loss of generality,  $A_i$  and  $A_{i+1}$  must point to the right in order to prevent an adjacent flag collision. This implies that  $A_n$  must also point to the right which results into a rigid frame collision.

A same argument holds with the argument beginning with the flag on the armature  $A_n$  pointing to the left. Thus there is no collision-free configuration with all armatures flagged.

Suppose there is an unflagged armature in a row. Turn all flags towards the nearest unflagged armature. If there are flags on  $A_1$  and  $A_n$ , point toward the interior thus they do not collide with the rigid frame. If there are flags on two consecutive armatures, they do not collide because the nearest unflagged armature cannot be between them. Therefore the row has a collision-free configuration.  $\square$

A logic engine is said to be *collision-free configurable* when every row has a collision-free configuration.

### 2.1.2.1 The Relationship of the Logic Engine and NAE3SAT

We show that given an boolean formula in 3-CNF form,  $\Phi$ , and a truth assignement,  $\tau$ , where the variables are given a truth assignment such that there is at least one true literal and one false literal in each clause of  $\Phi$ , then the corresponding logic engine to  $\Phi$  is collision-free configurable.

**Theorem 5.** *Given an instance of a NAE3SAT, it is a “yes” instance if and only if the corresponding logic engine is collision-free configurable.*

*Proof.* Suppose we have an instance of a NAE3SAT that is a “yes” instance. This implies that there is a truth assignment such that each clause contains a true and a false literal. Now consider the logic engine corresponding to this instance. We now show that it has a collision free configuration.

For variables that are true, configure the armatures such that the flags corresponding to the non-negated literals reside above the shaft and the flags that correspond to the negated literals reside below this shaft. For variables that are false, configure the armatures in the opposite orientation. Each clause corresponds to a pair of rows in the logic engine, one row for non-negated literals and one for negated literals. Because the NAE3SAT is a yes instance, every row contains at least one unflagged armature. By Lemma 1, every row has a collision-free configuration.

Suppose we have an instance of a NAE3SAT such that the corresponding logic engine has a collision-free configuration. By Lemma 1 every row at least one unflagged armature. The  $k^{th}$  clause is represented by the  $k^{th}$  rows above and below the shaft. If the literal  $x_j$  is found in clause  $C_k$ , then the armature is unflagged in that row. If the literal  $\bar{x}_j$  is found in clause  $C_k$ , then  $\bar{l}_{j,k}$  is unflagged. All flags corresponding to negated literals reside below the shaft and flags corresponding to non-negated literals reside above the shaft. All together we have that every clause has a true literal and a false literal. Thus, we have a ‘yes’ instance of the NAE3SAT.  $\square$

**Theorem 6.** *Deciding whether a logic engine is collision-free configurable is NP-Hard.*

*Proof.* In table ??, we defined the components of the logic engine in terms of polynomials in  $m$  and  $n$ . If there were a polynomial time algorithm that decides whether a given logic engine is collision-free configurable, then by Theorem 5 we would have a polynomial time algorithm to decide whether an instance of the NAE3SAT is a ‘yes’ instance. Since NAE3SAT is NP-Hard [10], there is no such algorithm unless  $P = NP$ .  $\square$

## 2.2 Logic Engines Represented as Polygonal Linkages

In the previous section, we introduced the logic engine. This section builds an analogous structure that is formed from a polygonal linkage and we may interchangeably say subcomponent for polygon. We can modify the mechanical structure of the logic engine to form a polygonal linkage. For a given a boolean formula,  $\Phi$ , in 3-CNF with  $n$  variables and  $m$  clauses, the rigid frame is broken into two polygons, each polygon on the extremity of the structure. The shaft is broken into  $n$  polygons. Each armature is broken into two parts, each part containing  $m$  subcomponents. In figure 2.7, each flag becomes a rectangle.

Figure 2.7: A logic engine realized as a polygonal linkage.

### 2.2.1 Construction of the Polygonal Linkage Logic Engine

Suppose we are given an boolean formula with  $m$  clauses and  $n$  variables in 3-CNF form,  $\Phi$ , we construct the polygonal linkage similarly to the logic engine. The corresponding polygonal linkage  $P_\ell = (\mathcal{P}, \mathcal{H})$  is detailed in Table ??.

Component	Height	Width	Quantity
Large Frame Subcomponent	$2 \cdot m$	1	2
Shaft Subcomponent	1	3	$n$
Armature Subcomponent	2	1	$2 \cdot m$
Flag	1	1.5	$2mn - 3m$

Table 2.2: The components of  $\mathcal{P}$  specified polynomially in terms of the size of the boolean formula  $\Phi$ .

The large frame subcomponents are hinged on the left most and right most shaft subcomponents. Each adjacent shaft subcomponents are hinged and each shaft subcomponent has two orientations, a reflection up and a reflection down about the shaft hinge points. On each shaft subcomponent there are two armature shaft subcomponents, one above the shaft subcomponent and one below the shaft subcomponent. By the two orientations of the shaft subcomponent, each armature subcomponent has two possible positions. Each armature comprises of  $m$  armature subcomponents that are hinged together; in total there are  $2n$  armatures. Each armature subcomponent has two orientations, a reflection left and a reflection right about the armature hinge points. Label the armature subcomponents on the  $j^{\text{th}}$  armature starting from the shaft by  $\ell_{j,1}, \dots, \ell_{j,n}$ .

on one side and  $\bar{\ell}_{j,1}, \dots, \bar{\ell}_{j,n}$  on the other side of the shaft. Attach a rectangular flag specified in Table ??, to some of these segments. Each segment is either flagged one or zero flags.

1. If the literal  $x_j$  is found in clause  $C_k$ , then  $\ell_{j,k}$  is unflagged.
2. If the literal  $\bar{x}_j$  is found in clause  $C_k$ , then  $\bar{\ell}_{j,k}$  is unflagged.

Each flag has two orientations with respect to armature it is attached to. Each flag has four potential positions, the flag can reflect left or right about the armature and the armature can reflect up or down about the shaft.

Figure 2.8: A polygonal linkage logic engine that corresponds to the boolean formula  $\Phi = C_1 \cap C_2 \cap C_3$ .

**Theorem 7.** *Given an instance of a NAE3SAT, it is a “yes” instance if and only if the corresponding polygonal linkage logic engine has a collision-free configuration.*

*Proof.* Suppose we have an instance of a NAE3SAT that is a “yes” instance. This implies that there is a truth assignment such that each clause contains a true and a false literal. Now consider the polygonal linkage logic engine corresponding to this instance. We now show that it has a collision free configuration.

For variables that are true, configure the armatures such that the flags corresponding to the non-negated literals reside above the shaft and the flags that correspond to the negated literals reside below this shaft. For variables that are false, configure the armatures in the opposite orientation. Each clause corresponds to a pair of rows in the polygonal linkage logic engine, one row for non-negated literals and one for negated literals. Because the NAE3SAT is a yes instance, every row contains at least one unflagged armature. By Lemma 1, every row has a collision-free configuration.

Suppose we have an instance of a NAE3SAT such that the corresponding polygonal linkage logic engine has a collision-free configuration. By Lemma 1 every row at least one unflagged armature. The  $k^{th}$  clause is represented by the  $k^{th}$  rows above and below the shaft. If the literal  $x_j$  is found in clause  $C_k$ , then the armature is unflagged in that row. If the literal  $\bar{x}_j$  is found in clause  $C_k$ , then  $\bar{\ell}_{j,k}$  is unflagged. All flags corresponding to negated literals reside below the shaft and flags corresponding to non-negated literals reside above the shaft. All together we have that every clause has a true literal and a false literal. Thus, we have a ‘yes’ instance of the NAE3SAT.  $\square$

## 2.3 Realizability Problems for Weighted Trees

In figure 2.9, we have a set of unit radius disks (circles) arranged in a manner that outlines regular, concentric hexagons.

Figure 2.9: A contact graph that resembles the shape of concentric hexagons.

**Problem 9** (Approximating Polygonal Shapes with Contact Graphs). For every  $\varepsilon > 0$  and polygon  $P$ , there exists a contact graph  $G = (V, E)$  such that the Hausdorff distance  $d(P, G) < \varepsilon$

Recall problems (??) and (??): given a positive weighted tree,  $T$ , is  $T$  the (ordered) contact graph of some disk arrangement where the radii are equal to the vertex weights. For now, we'll focus on a particular family of this problem space where the weighted trees can be realized as a *snowflake*. For  $i \in \mathbb{N}$ , the construction of the snowflake tree,  $S_i$ , is as follows:

- Let  $v_0$  be a vertex that has six paths attached to it:  $p_1, p_2, \dots, p_6$ . Each path has  $i$  vertices.
- For every other path  $p_1, p_3$ , and  $p_5$ :
  - Each vertex on that path has two paths attached, one path on each side of  $p_k$ .
  - The number of vertices that lie on the path attached to the  $j^{\text{th}}$  vertex of  $p_k$  is  $i - j$ .

A *perfectly weighted snowflake tree* is a snowflake tree with all vertices having weight  $\frac{1}{2}$ . A *perturbed snowflake tree* is a snowflake tree with all vertices having weight of 1 with the exception of  $v_0$ ; in a perturbed snowflake tree,  $v_0$  will have a radius of  $\frac{1}{2} + \gamma$ . For our analysis, all realizations of any snowflake, perfect or perturbed, shall have  $v_0$  fixed at origin. This is said to be the canonical position under Hausdorff distance of the snowflake tree.

Consider the graph of the triangular lattice with unit distant edges:

$$\begin{aligned} V &= \left\{ a \cdot (1, 0) + b \cdot \left( \frac{1}{2}, \frac{\sqrt{3}}{2} \right) : a, b \in \mathbb{Z} \right\} \\ E &= \{ \{u, v\} : \|u - v\| = 1 \text{ and } u, v \in V \} \end{aligned}$$

The following graph,  $G = (V, E)$  is said to be the *unit distance graph* of the triangular lattice. We can show that no two distinct edges of this graph are non-crossing. First suppose that there were two distinct edges that crossed,  $\{u_1, v_1\}$  and  $\{u_2, v_2\}$ . With respect to  $u_1$ , there are 6 possible edges corresponding to it, with each

Figure 2.10: The same contact graph as in figure 2.9 overlaid with the a perfectly weighted snowflake tree.

edge  $\frac{\pi}{3}$  radians away from the next. Neither edge crosses another; and so we have a contradiction that there are no edge crossings with  $\{u_1, v_1\}$ .

The perfectly weighted snowflake tree that is a subgraph over the *unit distance graph*,  $G = (V, E)$ , of the triangular lattice. To show this, for any  $S_i$ , fix  $v_0 = 0 \cdot (1, 0) + 0 \cdot \left(\frac{1}{2}, \frac{\sqrt{3}}{2}\right) = (0, 0) \in V$  at origin. Next consider the six paths attached from origin. Fix each consecutive path  $\frac{\pi}{3}$  radians away from the next such that the following points like on the corresponding paths:  $(1, 0) \in p_1$ ,  $\left(\frac{1}{2}, \frac{\sqrt{3}}{2}\right) \in p_2$ ,  $\left(-\frac{1}{2}, \frac{\sqrt{3}}{2}\right) \in p_3$ ,  $(-1, 0) \in p_4$ ,  $\left(-\frac{1}{2}, -\frac{\sqrt{3}}{2}\right) \in p_5$ ,  $\left(\frac{1}{2}, -\frac{\sqrt{3}}{2}\right) \in p_6$ . For  $S_i$ , there are  $i$  vertices on each path.

We define the six paths from origin as follows:

$$\begin{aligned}
 p_1 &= \{a \cdot (1, 0) = \vec{v} \mid a \in \mathbb{R}^+\} \\
 p_2 &= \left\{a \cdot \left(\frac{1}{2}, \frac{\sqrt{3}}{2}\right) = \vec{v} \mid a \in \mathbb{R}^+\right\} \\
 p_3 &= \left\{-a \cdot (1, 0) + a \cdot \left(\frac{1}{2}, \frac{\sqrt{3}}{2}\right) = a \cdot \left(-\frac{1}{2}, \frac{\sqrt{3}}{2}\right) = \vec{v} \mid a \in \mathbb{R}^+\right\} \\
 p_4 &= \{a \cdot (-1, 0) = \vec{v} \mid a \in \mathbb{R}^+\} \\
 p_5 &= \left\{a \cdot \left(-\frac{1}{2}, -\frac{\sqrt{3}}{2}\right) = \vec{v} \mid a \in \mathbb{R}^+\right\} \\
 p_6 &= \left\{a \cdot (1, 0) - a \cdot \left(\frac{1}{2}, \frac{\sqrt{3}}{2}\right) = a \cdot \left(\frac{1}{2}, -\frac{\sqrt{3}}{2}\right) \mid a \in \mathbb{R}^+\right\}
 \end{aligned}$$

For  $S_i$  there exists  $i$  vertices on each path. We shall denote the  $i^{\text{th}}$  vertex on the  $j^{\text{th}}$  path as  $v_{j,i}$ . For each path defined above, the paths are defined as a set of vectors,  $\vec{v} = a \cdot \vec{p}$  for some  $a \in \mathbb{R}^+$  and  $\vec{p} \in \mathbb{R}^2$ . By setting  $a = 1, 2, \dots, i$ , we obtain points that are contained in  $V$ . For  $j = 1, 3, 5$  and  $l = 1, \dots, i$ , there exists two paths attached to each vertex  $v_{j,l}$ . For  $S_i$ , each path attached to the  $k^{\text{th}}$  vertex of  $p_j$ , there are  $i - k$  vertices. We will need to show that each of the  $i - k$  vertices on each corresponding path are also in  $V$ .

The triangular lattice is symmetice under rotation about  $v_0$  by  $\frac{\pi}{3}$  radians. For each vertex  $v_{1,l}$  for  $l = 1, 2, \dots, i - k$ , we place two paths from it; the first path  $\frac{\pi}{3}$  above  $p_1$  at  $v_{1,l}$  and  $\frac{-\pi}{3}$  below  $p_1$  at  $v_{1,l}$  and call these paths  $p_{1,l}^+$  and  $p_{1,l}^-$  respectively. With respect to  $v_{1,l}$ , one unit along  $p_{1,l}^+$  is a point on the triangular lattice

and similarly so on  $p_{1,l}^-$ . Continuing the walk along these paths, unit distance-by-unit distance, we obtain the next point corresponding point on the triangular lattice up to  $i - k$  distance away from  $v_{1,l}$ . This shows that each of the  $i - k$  vertices on  $p_{1,l}^-$  and  $p_{1,l}^+$  are in  $V$ . By rotating all of the paths along  $p_1$  by  $\frac{2\pi}{3}$  and  $\frac{4\pi}{3}$ , we obtain the paths along  $p_3$  and  $p_5$  respectively, completing the construction.

### 2.3.1 On the Decidability of Problem 3

*Proof.* Consider a  $k \times (\sqrt{3}k)$  rectangle section of a triangular lattice, and place disks of radius 1 at each grid point as in Fig. 2.1. The contact graph of these disks contains 2-cycles. Consider the spanning tree  $T$  of the contact graph indicated in Fig. 2.2. The tree  $T$  decomposes into paths of collinear edges:  $T$  contains two paths along the two main diagonals, each containing  $2k - 1$  vertices; all other paths have an endpoint on a main diagonal. We now modify the disk arrangement to ensure that its contact graph is  $T$ . The disks along the main diagonal do not change. We reduce the radii of all other disks by a factor of  $1 - k^{-3}$  (as a result, they lose contact with other disks), and then successively translate them parallel in the direction of the shortest path in  $T$  to the main diagonal until the contact with the adjacent disk is reestablished. The Hausdorff distance between the union of these disks and the initial  $k \times (\sqrt{3}k)$  rectangle is clearly less than 1. However, the contact tree  $T$  with these radii no longer has a unique realization (small perturbations are possible). To show stability, we argue by induction on the hop distance from the central disk. There are  $O(i)$  disks at  $i$  hops from the central disk, most one which have radius  $(1 - k^{-3})^{\frac{1}{2}}$ . Since all radii are 1 or  $(1 - k^{-3})^{\frac{1}{2}}$ , the six neighbors of the central disk can differ from the regular hexagon by at most  $O(k)$ . Similarly, the disks at  $i$  hops from the center be off from the triangular grid pattern by  $O(i2^{k-3})$ , for  $i = 1, 2, \dots, k$ .  $\square$

## Chapter 3

### Realizability of Polygonal Linkages with Fixed Orientation

We begin the chapter with describing several gadgets that translates the associated graph  $A(\Phi)$  of a planar 3SAT instance. These gadgets will be used together to form a special hexagonal tiling that behaves in a similar nature to the logic engine of Chapter 2 but simulate a Planar 3-SAT and its associated graph. Together the gadgets will form what is called the auxiliary construction. The hexagonal tiling would then be used to prove the following theorem:

**Theorem 8.** *It is strongly NP-hard to decide whether a polygonal linkage whose hinge graph is a **tree** can be realized with counter-clockwise orientation.*

**Modifying the Associated Graph of a P3SAT** Given a P3SAT of  $n$  variables and  $m$  clauses with associated graph  $A(\Phi)$ . We construct a finite *honeycomb* grid  $H_{A(\Phi)}$  of regular hexagons over the plane centered at origin. Each hexagon of  $H_{A(\Phi)}$  is of unit side length and has a polynomial number of hexagons,  $s(n, m)$ . It is known that the size of the honeycomb is finite and can be determined by polynomials  $h(n, m) \times w(n, m)$  [5]. Let  $D = \max_{v \in V} \text{degree}(v)$  where  $V$  is the set of vertices of  $A(\Phi)$ . We modify the associated graph drawing  $A(\Phi)$  by overlaying it onto a honeycomb in the following way:

1. **Variable:** A vertex representing a variable shall encompass a consecutive set of hexagons along a horizontal line in the honeycomb. Every variable vertex  $v$  must encompass at least  $2 \cdot \text{degree}(v)$  consecutive hexagons but can encompass upto  $2 \cdot D$  consecutive hexagons.
2. **Clause:** A vertex representing a clause shall be a vertex of a hexagon in the honeycomb.
3. **Edge:** Edges of the associated graph  $A(\Phi)$  are paths from the variable  $x_i$  and clause  $C_j$ . An edge  $\{x_i, C_j\}$  of the associated graph is pairwise edge disjoint. An edge of the drawing shall traverse the edges of hexagons in a vertically or horizontally zigzagging manner in the honeycomb from the literal to the corresponding clause. The edges are drawn in a manner that best represents an orthogonal graph drawing over the honeycomb. The length of the edges are bounded above by  $6 \cdot (\ell_1(x_i, C_j) + D)$ . Edges traverse a hexagon in two edges vertically, three edges horizontally. When the edge transitions from a vertical to horizontal traversal, the edge traverses in over 4 edges about the hexagon.

Figure 3.1 illustrates an associated graph of a P3SAT overlayed on a honeycomb.

Figure 3.1: This is an instance of an associated graph for a P3SAT overlayed onto a honeycomb grid. This honeycomb graph could correspond to Boolean formula  $(\neg x_1 \vee \neg x_2 \vee x_4) \wedge (x_2 \vee \neg x_3 \vee x_4) \wedge (x_1 \vee \neg x_3 \vee \neg x_4)$ .

The honeycomb construction will act as preliminary concept that will be refined further in the Auxiliary Construction. We denote the associated graph overlayed on the honeycomb as  $\tilde{A}(\Phi)$ .

### 3.1 Auxiliary Construction

Given an instance  $\Phi$  of P3SAT with  $n$  variables and  $m$  clauses and its associated graph  $A(\Phi)$ , we construct a simply connected polygonal linkage  $(\mathcal{P}, H)$ , of polynomial size in  $n$  and  $m$ , such that  $\Phi$  is satisfiable if and only if  $(\mathcal{P}, H)$  admits a realization with fixed orientation.

We construct a polygonal linkage in two main steps: first, we construct an auxiliary structure where some of the polygons have fixed position in the plane (called *obstacles*), while other polygons are flexible, and each flexible polygon is hinged to an obstacle. Second, we modify the auxiliary construction into a polygonal linkage by allowing the obstacles to move freely, and by adding new polygons and hinges as well as an exterior *frame* that holds the obstacle polygons in place. All polygons in our constructions are regular hexagons or long and skinny rhombi because these are the polygons that we can “simulate” with disk arrangements in Section 1.4.

Let  $\Phi$  be a Boolean formula of P3SAT with variables  $x_1, \dots, x_n$  and clauses  $C_1, \dots, C_m$ , where  $A(\Phi)$  is the associated planar graph and  $\tilde{A}(\Phi)$  be corresponding honeycomb graph. We continue to modify  $\tilde{A}(\Phi)$  to form the auxiliary construction. For each hexagon in  $\tilde{A}(\Phi)$ , we scale the hexagons in the following way: first we fix the center of the hexagon and then scale (shrink) the hexagon; the hexagons in the honeycomb no longer touch each other and form corridors and junctions between the hexagons. Formally, let a *corridor* be a channel between two adjacent hexagons and a *junction* be a region where three corridors meet. We then finally re-scale this form of the honeycomb such that the side length of the hexagons are determined by polynomial of variable  $n$  and  $m$ ,  $N(n, m)$ , while preserving the corridors formed from the first scaling.

Figure 3.2: (a) A region of the honeycomb shown with scaling. The corridors and junctions formed from the first scaling is preserved after scaling the honeycomb grid to where the side lengths of the hexagon are  $N(n, m)$ . (b) The same region in (a) containing flexible hexagons.

Let the hexagons of Figure 3.2(a) be obstacle hexagons that are fixed at their centers. In Figure 3.2(b), we have smaller hexagons within some corridors and junctions. These hexagons are flexible hexagons. For each edge in  $\tilde{A}(\Phi)$ , we will replace that edge with flexible hexagons. Flexible hexagons are hinged at the vertex closest to origin and the side of the corridor (See Figure 3.3). Let  $t = 2N^3 + 1$  be the number of flexible hexagons in a corridor (see Figure 3.3). Scale the honeycomb such that the obstacle hexagons become regular hexagons of side length  $(5t - 1)/2 + \sqrt{3}$ , and then scale each obstacle hexagon independently from its center to a hexagon of side length  $(5t - 1)/2$  (see Figure ??).

Figure 3.3: (a) A corridor when all unit hexagons are in state R. (b) A corridor where all unit hexagons are in state L. (c) A junction where a small hexagon between two corridors ensures that at most one unit hexagon enters the junction from those corridors.

Between two adjacent obstacle hexagons, there is a  $\frac{5t-1}{2} \times \sqrt{3}$  rectangular corridor. Three adjacent corridors meet at a regular triangle, which we call a *junction*. For each corridor, there are two junctions adjacent to it; of these two junctions associated corridor, we denote the junction from which a flexible hexagon in the corridor enters into as the *active junction* (see Figure 3.4).

Figure 3.4: The active junction in (a) is the junction on the left and in (b) the active junction is on the right. The active junction is the junction in which a flexible hexagon enters from a corridor.

We next describe variable, clause, and transmitter gadgets. The basic building block of both variable and transmitter gadgets consists of  $t$  regular hexagons of side length 1 (*unit hexagons*, for short) attached to a wall of a corridor such that the hinges divide the wall into  $t + 1$  intervals of length  $(1, 2.5, \dots, 2.5, 1)$  as shown in Fig. 3.3(a-b) for  $t = 3$ .

Each junction is a regular triangle, adjacent to three corridors. In some of the junctions, we attach a small hexagon of side length  $\frac{1}{3}$  to one or two corners of the junction (see Fig. 3.3(c) and Fig. 3.6). Importantly, we have the following observation:

*Observation 1.* If a small hexagon is attached to a vertex between two corridors, then a unit hexagon can enter the junction from at most one of those corridors.

**Variable Gadget** The **variable gadget** for variable  $x_i$  is constructed as follows. Recall that variable  $x_i$  corresponds to a cycle in the associated graph  $\tilde{A}(\Phi)$ , which has been embedded as a cycle in the hexagonal tiling, with corridors and junctions. In each junction along this cycle, attach a small hexagon in the common boundary of the two corridors in the cycle. Figure 3.5 depicts a *variable gadget* in the hexagonal grid.

Figure 3.5: This depicts a variable gadget with  $x_1 = T$ . Carefully note that the flexible hexagons around  $x_1$  are in the state  $R$ . Corridors adjacent to two obstacles of a variable in the honeycomb do not have  $t$  flexible hexagons; these corridors simply have the flexible hexagons at the junctions.

Observation 2 and the small hexagons ensure that the state of any unit hexagon along the cycle determines the state of all other unit hexagons in the cycle. This property defines the binary variable  $x_i$ : If  $x_i = T$ , then all unit hexagons in the top horizontal corridors are in state  $R$ ; and if  $x_i = F$ , they are all in state  $L$ . When a

Figure 3.6: The common junction of a variable gadget and a transmitter gadget. (a) When  $x_i = T$ , a hexagon of the transmitter may enter the junction of the variable gadget. (b) When  $x_i = T$ , the transmitter gadget has several possible realizations. (c) When  $x_i = F$ , no hexagon from the transmitter enters a junction of the variable gadget.

binary variable  $x_i = T$ , we will say that the variable is in state  $R$  and that the cycle of small hexagons around the variable gadget are in a “clockwise direction”. When a binary variable  $x_i = F$ , we will say that the variable is in state  $L$  and that the cycle of small hexagons around the variable gadget are in a “counter-clockwise direction”.

**Clause Gadget** Recall that a clause from a Boolean formula  $\Phi$  in 3-CNF has three literals. If  $\Phi$  is a ‘yes’ instance, then at least one literal in every clause of  $\Phi$  is true. We construct the clause gadget to model this fact about Boolean formulas in 3-CNF.

The **clause gadget** lies at a junction adjacent to three transmitter gadgets (see Fig. 3.7 and Section 3.1). At such a junction, we attach a unit line segment to an arbitrary vertex of the junction, and a small hexagon of side length  $\frac{1}{3}$  to the other end of the segment. If unit hexagons enter the junction from all three corridors (i.e., all three literals are false), then there is no space left for the small hexagon.

Figure 3.7: (a-b) A clause gadget  $(x_i \vee x_j \vee x_k)$  is realizable when at least one of the literals is TRUE. (c) The clause gadget cannot be realized when all three literals are FALSE.

But if at most two unit hexagons enter the junction (i.e., one of the literals is true), then the unit segment and the small hexagon are realizable.

**Transmitter Gadget** In the planar 3-SAT graph  $A(\Phi)$ , every variable vertex has an associated cyclic order of edges. In Figure 3.8(b), we have variable vertex  $x_i$  with counter-clockwise cyclic order of edges  $(\{x_i, C_1\}, \{x_i, C_2\}, \{x_i, C_3\})$ .

Figure 3.8: (a) The large vertices on the variable gadget indicate the the corresponding junction of where a transmitter gadget corresponding to an edge from  $x_i$  to a clause in  $\Phi$ . (b) The corresponding edges about  $x_i$  of the bipartite planar graph  $A(\Phi)$  and shows the cyclic order of edges about  $x_i$ .

The order in which transmitter gadgets about the obstacle hexagons of a variable gadget follows from the counter-clockwise cyclic order of  $A(\Phi)$ . A **transmitter gadget** is constructed for each edge  $(x_i, C_j)$  of the graph  $A(\Phi)$ ; it consists of a sequence of junctions and corridors from a variable gadget's junction to a clause junction. For each variable-clause edge of  $A(\Phi)$ , there are two possible junctions of for the corresponding transmitter gadget. Figure 3.8(a) shows an example of the possible junctions (indicated with large vertices on the appropriate obstacle hexagons of the variable gadget) in which a transmitter gadget can be connected that corresponds to an edge in Figure 3.8(b). Choosing the junction of the variable gadget to attach a transmitter gadget depends on the truth value of the variable and the type of literal found in the clause.

- (a) For an edge  $(x_i, C_j)$  of the graph  $A(\Phi)$ , if the non-negated literal of  $x_i$  exists in  $C_j$  where  $x_i = T$ , attach the transmitter gadget to the non-active junction (see Figure 3.9(a)).
- (b) For an edge  $(x_i, C_j)$  of the graph  $A(\Phi)$ , if the negated literal of  $x_i$  exists in  $C_j$  where  $x_i = T$ , attach the transmitter gadget to the active junction (see Figure 3.9(b)).
- (c) For an edge  $(x_i, C_j)$  of the graph  $A(\Phi)$ , if the negated literal of  $x_i$  exists in  $C_j$  where  $x_i = F$ , attach the transmitter to the non-active junction (see Figure 3.9(c)).
- (d) For an edge  $(x_i, C_j)$  of the graph  $A(\Phi)$ , if the non-negated literal of  $x_i$  exists in  $C_j$  where  $x_i = F$ , attach the transmitter gadget to the active junction (see Figure 3.9(d)).

Figure 3.9: These four figures depict an example of placing a transmitter gadget corresponding to edge  $\{x_i, C_j\}$ .

Figure 3.9 shows an example of each rule on choosing a junction to attach a transmitter gadget. The first column transmits a “true” value between the variable gadget and clause junction. The second column transmits a “false” value between the variable gadget and clause junction. The variable gadgets in the first row are in state  $R$ , i.e. variable  $x_i = T$ . The variable gadgets in the second row are in state  $L$ , i.e. variable  $x_i = F$ .

For each junction in the transmitter gadget, we attach a small hexagon in the junction as shown in Figure 3.6 except at the clause junction.

If the literal  $x_i$  (resp.,  $\bar{x}_i$ ) appears in  $C_j$ , then we attach a small hexagon to the corner of this junction such that if  $x_i = F$  (resp.,  $\bar{x}_i = F$ ), then the unit hexagon of the transmitter gadget cannot enter this junction.

A variable gadget for vertex  $v$  in the associated graph of a P3SAT Boolean formula encompasses at least  $2 \cdot \deg(v)$  consecutive obstacle hexagons. The arrangement of the consecutive obstacle hexagons are in staggered fashion about a horizontal line where there are at least  $\deg(v)$  obstacle hexagons in the upper portion of the staggering arrangement and at least  $\deg(v)$  obstacle hexagons in the lower portion of the staggering arrangement.

### 3.1.1 Functionality of the Auxiliary Construction and Gadgets

Section 3.1 is a formal description of the auxiliary construction and its gadgets. This subsection covers the underlying assumptions and proofs about the functionality of the auxiliary construction. The first observations

about the functionality of the auxiliary construction are about the flexible hexagons.

- Observation 2.* (1) If the leftmost hexagon is in state R, then all  $t$  hexagons are in state R, and the rightmost hexagon enters the junction on the right of the corridor.
- (2) Similarly, if the rightmost hexagon is in state L, then all  $t$  hexagons are in state L, and the leftmost hexagon enters the junction on the left of the corridor.

The proof of the Observation 2 is similar to the proof of Lemma 1 regarding a row in a logic engine having a collision-free configuration.

*Proof.* Suppose the leftmost hexagon,  $h_1$ , is in state R in a corridor. Denote the  $t$  flexible hexagons in a corridor as  $h_1, h_2, \dots, h_t$  from leftmost to rightmost respectively.  $h_2$  must be in state R otherwise we result in a collision between  $h_1$  and  $h_2$ . Without loss of generality,  $h_i$  and  $h_{i+1}$  must be in a state R in order to prevent an adjacent flexible hexagon collision. This implies that rightmost flexible hexagon  $h_t$  must also be in state R; this implies that  $h_t$  enters the junction that is on the right of the corridor.

Similarly, suppose the rightmost hexagon,  $h_t$ , is in state L in a corridor. Denote the  $t$  flexible hexagons in a corridor as  $h_1, h_2, \dots, h_t$  from leftmost to rightmost respectively.  $h_{t-1}$  must be in state L otherwise we result in a collision between  $h_t$  and  $h_{t-1}$ . Without loss of generality,  $h_i$  and  $h_{i+1}$  must be in a state L in order to prevent an adjacent flexible hexagon collision. This implies that rightmost flexible hexagon  $h_1$  must also be in state L; this implies that  $h_1$  enters the junction that is on the left of the corridor.  $\square$

The flexible hexagons of the auxiliary construction help communicate the boolean value of a variable gadget to the rest of the auxiliary construction. This communication property of the flexible hexagons in a corridor is analogous to the flags in a row of a logic engine.

Each junction is a regular triangle, adjacent to three corridors. In some of the junctions, we attach a small hexagon of side length  $\frac{1}{3}$  to one or two corners of the junction (see Fig. 3.3(c) and Fig. 3.6). Importantly, we have the following observation:

*Observation 3.* If a small hexagon is attached to a vertex at a junction between two adjacent corridors, then a flexible hexagon can enter the junction from at most one of those corridors.

*Proof.* Suppose there is a small hexagon attached to a vertex at a junction between two adjacent corridors. Suppose it is not that case that a flexible hexagon can enter the junction from at most one of these adjacent corridors. Then there are two flexible hexagons entering the junction, one from each adjacent corridor. The angular sum of the vertex about the adjacent corridors consists of the obstacle hexagon, both flexible hexagons, and the small unit hexagon. Each angle of each hexagon is  $\frac{2\pi}{3}$  radians, totalling to an angular sum of  $\frac{8\pi}{3} > 2\pi$ . This is a contradiction with the total angular sum of a vertex on the plane to be  $2\pi$ .  $\square$

Observation 2 and the small hexagons ensure that the state of any unit hexagon along the cycle determines the state of all other unit hexagons in the cycle. This property defines the binary variable  $x_i$ : If  $x_i = T$ , then all unit hexagons in the top horizontal corridors are in state R; and if  $x_i = F$ , they are all in state L.

**Lemma 2.** *Hexagons in a clause junction have a non-overlapping placement if and only if at least one of the three literals is true.*

*Proof.* Suppose we have a hexagons in a clause junction that have a non-overlapping placement. To show that there is at least one of the three literals is true, we do a proof by contradiction. Suppose all literals of the clause are false.

**The Activation Process** The transmitter gadget for each literal is placed on an active junction of the variable gadget. This junction is “activated” by the variable gadget. By Observation 3, the flexible hexagon nearest of the transmitter gadget to the variable gadget does not enter the transmitter-variable junction. By Observation 2 and the state of the flexible hexagon nearest of the transmitter gadget to the variable gadget implies that the flexible hexagons in that transmitter corridor activate the junction opposite the transmitter-variable junction. The subsequent flexible hexagons in the transmitter gadget corridors have the same state of the flexible hexagon in the transmitter gadget nearest of the transmitter-variable junction by Observations 2 and 3. This activation process continues up to the clause junction and the flexible hexagon in the transmitter gadget nearest the clause junction enters the clause junction.

If all literals of the clause are false, then all flexible hexagons in each transmitter gadget nearest their clause junction enters the clause junction, as shown in Figure 3.7(c) which show the small hexagon overlapping flexible hexagons in the clause junction, a contradiction with hexagons in the clause junction have a non-overlapping placement.  $\square$

For a variable gadget  $x_i$ , place horizontal axis  $h$  at mid-height of the gadget. Then we have the following lemma:

**Lemma 3.** *If variable  $x_i = T$ , then all flexible hexagons above  $h$  are in state  $R$  and all flexible hexagons below  $h$  are in state  $L$ ; if variable  $x_i = L$ , then all flexible hexagons above  $h$  are in state  $L$  and all flexible hexagons below  $h$  are in state  $R$ .*

*Proof.* Suppose we have two adjacent corridors  $k_i$  and  $k_{i+1}$  sharing junction  $J_i$  and without loss of generality,  $k_i$  is the left most corridor. Observation 3 implies that there can only be one hexagon entering  $J_i$  from either  $k_i$  or  $k_{i+1}$ . If the hexagon that enters  $J_i$  is from corridor  $k_i$ , then this hexagon has state  $R$  and all flexible hexagons in corridor  $k_i$  are in state  $R$  by Observation 2. Since the nearest flexible hexagon of corridor  $k_{i+1}$  cannot enter the junction  $J_i$ , it must also have state  $R$ . All flexible hexagons in corridor  $k_{i+1}$  are in state  $R$  by Observation 2.

The argument is similar if the hexagon entering  $J_i$  is from corridor  $k_{i+1}$  and all flexible hexagons in both corridors  $k_i$  and  $k_{i+1}$  have state  $L$ .

Because variable gadgets form a simple cycle of corridors and junctions  $(k_1, J_1, k_2, J_2, \dots, k_n, J_n)$  and the argument above, all flexible hexagons about a variable gadget have the same state.  $\square$

Suppose there is an edge  $\{x_i, C_j\}$  in the graph  $A(\Phi)$ .

**Lemma 4.** *If  $x_i = T$  and its negated literal is in  $C_j$ , then a flexible hexagon enters into the clause gadget of  $C_j$ , otherwise it need not enter; if  $x_i = F$  and its non-negated literal is in  $C_j$ , then a flexible hexagon enters into the clause gadget of  $C_j$ , otherwise it need not enter.*

*Proof.* See the paragraph “**Activation Process**” in the proof of Lemma 2.  $\square$

**Lemma 5.** *For every instance  $\Phi$  of P3SAT, the above polygonal linkage with flexible and obstacle polygons has the following properties: (1) it has polynomial size; (2) its hinge graph is a forest; (3) it admits a realization such that the obstacle polygons remain fixed if and only if  $\Phi$  is satisfiable.*

*Proof.* Suppose we have an instance  $\Phi$  of P3SAT with  $m$  variables and  $n$  clauses with a corresponding associated graph  $A(\Phi) = (V, E)$  and it is satisfiable. We need to show the following three properties about its corresponding auxilliary construction: it has polynomial size, its hinge graph is a forest, and it admits a realization such that the obstacle polygons remain fixed.

(1) We can bound the number of obstacle hexagons to represent a variable gadget by  $2D$ , where  $D = (\max_{v \in V} \deg(v))$ . The number of clause junctions is  $n$ . To give an upper bound on the number of flexible hexagons in the auxiliary construction, we have to account for the flexible hexagons in the transmitter gadgets, the extra hexagons found in junctions, and the flexible hexagons around the variable gadgets.

Recall that the number of flexible hexagons in a corridor are  $t = 2N(m, n)^3 + 1$  where  $N(m, n)$  is a polynomial. Recall that the drawing of  $A(\Phi)$  have edges drawn in vertically and horizontally and can join at some “elbow”. The distance can be measured in the  $\ell_1$  norm. Similarly in the honeycomb construction, the flexible hexagons zig-zig vertically and horizontally through out honeycomb. The number of corridors about an obstacle hexagon is 6. To give a generous upper bound on the number of flexible hexagons in a transmitter gadget, is  $6 \cdot t \cdot \ell_1(v_i, C_j)$ , assuming each obstacle hexagon is of unit height.

The number of junctions in the auxiliary construction is the number of junctions to form all variable gadgets, transmitter gadgets, and clause gadgets. We know there are at most  $2 \cdot D$  obstacle hexagons to form each variable gadget and 6 junctions for each obstacle hexagon. Therefore an upper bound for the number of flexible hexagons around variable gadgets is  $m \cdot 6 \cdot t \cdot 2 \cdot D$ . The upper bound for the number of junctions in a transmitter gadget is  $6\ell_1(v_i, C_j)$ . Thus, the upper bound of all junctions in all transmitter gadgets is

$$6 \cdot \sum_{\{v_i, C_j\} \in E} \ell_1(v_i, C_j).$$

The upper bound on the total number of flexible hexagons is

$$m \cdot 6 \cdot t \cdot 2 \cdot D + 6 \cdot \sum_{\{v_i, C_j\} \in E} \ell_1(v_i, C_j).$$

(2) Recall that a forest is a disjoint union of trees. By construction, each flexible hexagon is hinged to exactly one obstacle hexagon. There are no hinges between obstacle hexagons. Consequently, each component of the hinge graph is a star, where the center corresponds to an obstacle hexagon and the leafs corresponds to the flexible hexagons attached to it.

(3) The final statement is to show an if and only if statement: it admits a realization such that the obstacle polygons remain fixed if and only if  $\Phi$  is satisfiable.

Suppose  $\Phi$  is satisfiable. Each variable has a boolean value and we can encode the corresponding auxiliary construction accordingly. For each variable, we encode the boolean value by the state of the flexible hexagons surrounding the variable gadget to  $R$  or  $L$ . Lemma 3 shows that the corridors and junctions around the variable gadget are realizable. Lemma 4 also show that for each transmitter gadget, every corridor and junction are also realizable. Lemma 2 shows that there is at least one hexagon in the clause junction and that the clause is realizable. Thus all parts of the auxiliary construction realizable and these we have a realization.

Suppose the construction admits a realization such that the obstacle polygons remain fixed. Each variable gadget's flexible hexagons are configured to state  $L$  or  $R$ . The variable's corresponding state correspond to the variable's truth value, i.e.  $R$  for true and  $L$  for false. Using Lemma 3, the boolean state of the variable gadget is transmitted to all transmitter gadgets associated to it. Each clause is realizable and so for every clause, there exists one true literal in the clause corresponding to a variable by Lemma 2. If every clause has some true literal, then the corresponding 3-CNF boolean formula is satisfiable.  $\square$

**Modified Auxiliary Construction** We modify the auxiliary construction allowing all polygons to move freely, and by adding extra polygons and hinges so that the hinge graph becomes a *tree*, and the size of the construction remains polynomial. Recall that our auxiliary construction is based on a polynomial section of the hexagonal grid, using obstacle hexagons of side lengths  $(5t - 1)/2$ , unit hexagons (of side length 1), and small hexagons of side length  $\frac{1}{3}$ . We modify it in 3 steps as follows.

1. Move the obstacle hexagons apart such that the width of each corridor increases from  $\sqrt{3}$  to  $\sqrt{3} + 1/(100N)$ .
2. Replace the unit segment in each the clause gadget by a skinny rhombus of diameter 1.1 and width  $1/(200N)$ .
3. Consider a large (polynomial-size) regular hexagon  $R$  that contains all gadgets in our construction, and enclose  $R$  by a *frame* of 6 congruent regular hexagons, as shown in Fig. 3.10(a), hinged together in a path.
4. Connect the frame and the obstacles in  $R$  into a simply connected polygonal linkage: In each obstacle hexagon, the bottom or bottom-left side is adjacent to the frame or to a corridor. Introduce a hinge at the midpoint of one such side in each obstacle hexagon. If this side is adjacent to the frame, then attach the hinge to the frame. Otherwise, the hinge is attached to a new *connector* polygon: a skinny rhombus of diameter 1 and width  $1/(200N)$ . The far corner of each rhombus is hinged to the unit hexagon in the middle of the corridor at shown in Fig. 3.10(b).

Figure 3.10: (a) A frame (built of 6 hinged regular hexagons) encloses a hexagonal tiling, and vertical paths connect all obstacle hexagons to the frame. (b) A corridor is widened to  $\sqrt{3} + 1/N^2$ . A connection between two adjacent obstacle hexagons is established via a skinny rhombus.

We obtain a simply connected polygonal linkage. We now allow the obstacle hexagons to move freely, and call their original fixed position *canonical*. (3) We may assume without loss of generality that the frame is at its original position. It is enough to show that the obstacle hexagons are still confined to an  $1/N$ -neighborhood of their canonical position, then it follows that the polygonal linkage is realizable if and only if  $\Phi$  is satisfiable.

**Lemma 6.** *For every instance  $\Phi$  of P3SAT, the above polygonal linkage with flexible and obstacle polygons has the following properties: (1) it has polynomial size; (2) the hinge graph of the modified auxiliary construction is a tree; (3) it admits a realization such that the obstacle polygons has a maximal displacement from canonical position if and only if  $\Phi$  is satisfiable.*

*Proof.* (1) We can bound the number of obstacle hexagons to represent a variable gadget by  $2D$ , where  $D = (\max_{v \in V} \deg(v))$ . The number of clause junctions is  $n$ . To give an upper bound on the number of flexible hexagons in the auxiliary construction, we have to account for the flexible hexagons in the transmitter gadgets, the extra hexagons found in junctions, and the flexible hexagons around the variable gadgets.

Recall that the number of flexible hexagons in a corridor are  $t = 2N(m, n)^3 + 1$  where  $N(m, n)$  is a polynomial. Recall that the drawing of  $A(\Phi)$  have edges drawn in vertically and horizontally and can join at

some “elbow”. The distance can be measured in the  $\ell_1$  norm. Similarly in the honeycomb construction, the flexible hexagons zig-zig vertically and horizontally through out honeycomb. The number of corridors about an obstacle hexagon is 6. To give a generous upper bound on the number of flexible hexagons in a transmitter gadget, is  $6 \cdot t \cdot \ell_1(v_i, C_j)$ , assuming each obstacle hexagon is of unit height.

The number of junctions in the auxiliary construction is the number of junctions to form all variable gadgets, transmitter gadgets, and clause gadgets. We know there are at most  $2 \cdot D$  obstacle hexagons to form each variable gadget and 6 junctions for each obstacle hexagon. Therefore an upper bound for the number of flexible hexagons around variable gadgets is  $m \cdot 6 \cdot t \cdot 2 \cdot D$ . The upper bound for the number of junctions in a transmitter gadget is  $6\ell_1(v_i, C_j)$ . Thus, the upper bound of all junctions in all transmitter gadgets is

$$6 \cdot \sum_{\{v_i, C_j\} \in E} \ell_1(v_i, C_j).$$

The upper bound on the total number of flexible hexagons is

$$m \cdot 6 \cdot t \cdot 2 \cdot D + 6 \cdot \sum_{\{v_i, C_j\} \in E} \ell_1(v_i, C_j).$$

For each corridor, there is one skinny rhombus attached to one flexible hexagon in the corridor. If the number of corridors is bounded polynomially, then the number of skinny rhombi is bounded by the same bound of the corridor.

(2) Recall that in the original auxiliary construction is a forest. each obstacle hexagon with hinged flexible hexagons (and small hexagons) is disjoint from the remainder of the the construction. The skinny rhombi in the modified auxiliary construction connect the disjointed trees to form one tree.

(3)

1. Suppose the honeycomb grid has a total height of  $h$
2. the number of obstacle hexagons along a vertical path from the top/bottom of the grid is  $K$  and the sum of their heights is  $K \cdot h_O$ .
3. the different of (1) and (2) is  $h - K \cdot h_O$ .
4. ???
5. profit

Maclaurin series of  $\tan^{-1}$  is:

$$x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7} + \frac{x^9}{9} + O(x^{10})$$

$$\alpha \leq \tan^{-1} \frac{3}{N} \leq M = \frac{3}{N}$$

$$\lim_{x \rightarrow 0} \tan^{-1} x = x$$

## Chapter 4

### Disk Arrangement

#### 4.1 Properties for Weighted Trees and Polygonal Linkages

In order to perform our analysis for weighted trees and polygonal linkages, we'll want to use a suitable metric. The usual Euclidian distance will not suffice for this analysis and so we turn to the Hausdorff distance.

**Hausdorff Distance** Let  $A$  and  $B$  be sets in the plane. The *directed Hausdorff distance* is

$$d(A, B) = \sup_{a \in A} \inf_{b \in B} \|a - b\| \quad (4.1)$$

$h(A, B)$  finds the furthest point  $a$  in  $A$  from any point in  $B$ . *Hausdorff distance* is

$$D(A, B) = \max \{d(A, B), d(B, A)\} \quad (4.2)$$

Figure 4.1: An illustrative example of  $d(X, Y)$  and  $d(Y, X)$  where  $X$  is the inner curve, and  $Y$  is the outer curve.

**$\epsilon$ -approximation** The weighted graph,  $G$ , is an  $\epsilon$ -approximation of a polygon  $P$  if the Hausdorff distance between every realization such realization of  $G$  as a contact graph of disks and a congruent copy of  $P$  is at most  $\epsilon$ . A weighted graph  $G$  is said to be a  $O(f(x))$ -approximation of a polygon  $P$  if there is a positive constant  $M$  such that for all sufficiently large values of  $x$  the Hausdorff distance between every realization such realization of  $G$  as a contact graph of disks and a congruent copy of  $P$  is at  $M \cdot |f(x)|$ . A weighted graph  $G$  is said to be a *stable* if it has the property that for every two such realizations of  $G$ , the distance between the centers of the corresponding disks is at most  $\epsilon$  after a suitable rigid transformation.
